The 1991 forms now rely on national vs. regional normative (nonreferred) samples. Although the CBCL and YSR are routinely self-administered in clinical application, the CBCL normative data and some undefined proportion of the YSR norms were obtained through interview of the appropriate informant. It may be that the interactive process of interview administration of the CBCL inhibited informant response to checklist items. For example, six of eight parent informant scales obtained average normative raw scores of less than 2 with associated restricted scale variance. It is important to note that increased problem behavior scale elevation reflects increased problems, although these scales do not consistently extend below 50*T*. Because of the idiosyncratic manner in which *T* scores are assigned to scale raw scores, it is useful to follow each manual's suggestion to use scale raw scores, rather than *T* scores, in research applications. It is difficult to determine the interpretive meaning of checklist *T* scores, the derivation of which has been of concern (Lachar, 1993; Kamphaus & Frick, 1996; Kline, 1994, 1995). Scale values under 70*T* are normalized and therefore compressed and unrepresentative of actual scale score distributions in the normative sample. Values above 70*T* have been arbitrarily assigned by the checklists' author with the goal of placing all possible scale scores evenly across available profile space and do not represent any specific probabilistic or statistical relationship with scores under 70*T*. The CBCL checklists do not provide any measure of informant response set or protocol validity. Not only is the identification of either symptom denial or random response problematic, but the *T* score assignment process above 70*T* can result in protocols that are the result of a response set to exaggerate problems but appear as valid estimates of child adjustment.

4.13.2.3.1 Child Behavior Checklist/4–18 (CBCL) and 1991 Profile

Parents complete a four-sided pamphlet and clinicians complete one of two two-sided profile forms (one for girls, one for boys). Norms are provided for two age ranges (4–11 and 12–18 for problem scales, 6–11 and 12–18 for competence scales) separate by gender. Rated competence items are organized by manifest content into three narrow scales (Activities, Social, and School) which are then summed into a total score. Parents are asked to list and then rate (frequency, performance level) a child's participation in sports, hobbies, organizations, and chores. Parents also describe the child's friendships, social interactions, performance in academic subjects, need for special assistance in school, and history of retention in grade. As standard scores for these scales increase with demonstrated ability, a borderline range is suggested at 30–33*T* and the clinical range is designated at $T < 30$. It has been suggested that a child's social and economic opportunities as well as race and ethnicity significantly affect these values (Drotar et al., 1995). These scales have also been compared to those of the PIC in their ability to predict adaptive level as defined by the Vineland Adaptive Behavior Scales (Pearson & Lachar, 1994).

The behavior problem scales consist of one to eight word descriptions ("Overtired," "Argues a lot," "Feels others are out to get him/her"). Appendix A of the 1991 CBCI provides scoring directions for the 21 items that incorporate informant individual comment. Clinicians must understand checklist content and child psychopathology to correctly score these items. For example, item 113 is "Please write in any problems your child has that were not listed above." The person who scores the checklist must review the up to three examples that can be elicited, determine if they duplicate other checklist content, and then score the one unique symptom that receives the highest rating (Very True or Often True rather than Somewhat or Sometimes True). The importance of this issue cannot be minimized as almost all items of the Thought Problems scale for all three informants are provided in this format. Syndrome T scores are interpreted as borderline at 67–70T and in the clinical range at $T > 70$. There is some evidence, however, which suggests that ADHD and comorbid conditions are more accurately identified with a lower cutting point (Biederman et al., 1993; Chen, Faraone, Biederman, & Tsuang, 1994; Faraone, Biederman, Weber, & Russell, 1998; Steingard, Biederman, Doyle, & Sprich-Buckminster, 1992). The Total Problem scale is interpreted as borderline at 60–63T and in the clinical range at $T > 63$. Although the summary Internalizing and Externalizing scales are discussed in terms of their relative elevation when compared to each other, absolute interpretive guidelines are not provided.

Profile and pamphlet formats facilitate review of response content at the item level. Although scales are developed to overcome the unreliability of item responses, CBCL content may be important for a number of reasons. On several scales a "very true or often true" response to as few as two or three statements places a scale T score in the clinical range. When scales are limited in length and relatively heterogeneous in content, the same scale elevation can be generated by quite different observational content. A casual review of scale content reveals some inconsistencies that follow into TRF and YSR dimensions. Obsessions and compulsions, often associated with anxiety disorders, join strange ideas, behaviors, and hallucinations on the Thought Problems dimension; "Nervous, highstrung, or tense" appears on Attention Problems as well as Anxious/Depressed; while "Unhappy, sad, or depressed" appears on Withdrawn as well as Anxious/Depressed. The 19–25 item Aggressive Behavior dimension appears to have a number of items that appear to be more readily associated with ADHD phenomena than any "aggressive" dimension: "Demands a lot of attention," "Showing off or clowning," "Talks too much," as well as two items only on the TRF: "Talks out of turn," and "Disrupts class discipline." These observations suggest that although a factor analysis can identify clinically meaningful dimensions, subsequent efforts may be necessary to assure the stability of item scale placement. (See Erford (1996) for an example of an attempt to replicate the structure of a short factor-derived teacher rating form.) It may also be useful to review the item by dimension correlation matrix that underlies each factor analysis to determine the appropriateness of each item's scale placement.

4.13.2.3.2 Teacher's Report Form (TRF) and 1991 Profile

The TRF emerged from the CBCL and the comparability of the 120 symptom/problem items is readily apparent, as are the eight syndrome, two broad-band, and one summary score. However, comparison of the competence sections of the TRF and the CBCL reveals a marked difference. TRF measures are based upon very limited data: an average rating of academic performance based on up to six subjects identified by the teacher, individual seven-point ratings on four topics (how hard working, behaving appropriately, amount learning, and how happy), as well as a summary score from these four items. The TRF designates a borderline interpretive range for the mean academic performance and the summary score of 40–37T, with clinical range of $T < 37$. Even a cursory review of the TRF pamphlet suggests that the equivalence of CBCL and TRF forms was given priority over collection of teacher observations that would be unique to the classroom and the school environment. If observations of social and academic skills were integrated into the TRF, the teacher could also provide estimates of adaptive behaviors necessary for success in the classroom.

4.13.2.3.3 Youth Self-report (YSR) and 1991 Profile

The elements of this self-report measure have most of the basic characteristics of the CBCL and TRF. The YSR requires a fifth grade reading ability and provides competence and problem behavior standard scores normed separately by gender for the age range of 11 through 18. Seven adaptive competency items are scored for Activities, Social, and a Total Competence scale. The YSR manual's Appendix A is necessary to score these items (the addition of scoring examples would be very useful). These seven multipart items tap competence and level of involvement in sports, activities, organizations, jobs, and chores. Items also provide self-report of academic achievement, interpersonal adjustment, and level of socialization.

The remainder of the pamphlet presents 120 statements in which 16 are socially desirable items endorsed by most students. These items replace potential YSR equivalents of CBCL items that presented either problem behaviors of very young children or school-related difficulties. The presence of these 16 unscored items represents an unused opportunity to develop a semantic inconsistency scale to measure random response or inadequate comprehension, or some sort of defensiveness measure. The lack of validity scales in this self-report of symptoms and problems is considered problematic by several reviewers (Kamphaus & Frick, 1996; Kline, 1995; Lachar, 1993). Two reviewers cite literature that documents the YSR's diagnostic insensitivity (Kamphaus & Frick, 1996; Merrell, 1994).

The eight problem scales range from 50 to $100T$, with $67–70T$ assigned the borderline range and $T > 70$ the clinical range. The Activities and Social Competency scales range from 55 to $20T$, while the Total Competence score is profiled from 10 to $80T$. Activities and Social are in the borderline range from 33 to $30T$, while the clinical range includes scales $< 30T$. On the Total Competence scale, T scores of 40–37 are designated as borderline, while T scores < 37 form the clinical range.

4.13.2.3.4 Commentary

The CBCL, TRF, and YSR format is responsible for both the broad success that these instruments have achieved as well as their shortcomings. Each form can be completed in 10–20 minutes and appears easily scored (if competence items and items requiring informant explanation are avoided). Brevity is especially attractive for research applications in which subject and human subject research committee tolerance for multiple measures is of specific concern. Scoring software provided by the CBCL/TRF/YSR author facilitates not only the processing of individual instruments, but provides estimates of agreement over multiple reports on the same instrument, as well as agreement across different instruments.

It is almost certain that the CBCL, TRF, and YSR common format will stimulate meaningful across-informant research that will document the effect of item and scale content as well as informant characteristic (gender, age, ethnicity, clinical status) on both degree of agreement and relative contribution to the diagnostic process. Such research should generate useful guidelines for the clinical application of these instruments. On the other hand, the primary focus on parallel dimensions and consistency in the problem behavior scale construction technique limits collection of informant-specific observation. The other instrument families presented in this chapter vary in dimensions assessed to some degree to facilitate the collection of such information.

The decision to revise scales without modification of the original problem statement pool assured continuity but at the same time restricted potential improvement. These forms continue to demonstrate their original limitations in psychometric character. It is difficult to understand why the author has taken an idiosyncratic and statistically unsupportable approach both in subjecting summations of symptoms to a normalization process and in providing profiles that assign T scores to all physically possible raw scores. Certainly problematic item performance in the form of restricted range in symptom frequency within these normative samples is at the core of attempts to modify score distributions to improve psychometric performance. The absence of validity scales continue to present random, defensive, and exaggerated protocols as profiles that should be interpreted rather than excluded from this process.

The most remarkable observation, in contrast to the continuing research growth of CBCL/TRF/YSR application, is the apparent absence of interpretive guidelines for the clinician (certainly percentiles derived from normative samples do not provide evidence of scale meaning beyond that suggested by manifest item content). These 1991 manuals present as primary evidence of validity that items and scales differentiate clinical and normative samples. Such evidence is only clinically useful if such a decision is frequently made in practice. (Clinicians know whether a student has or has not been referred for an evaluation.) Certainly there should be sufficient opportunity within 2000 published studies to document the answers to specific clinically relevant questions. (Indeed, it is quite clear that much of the results of research in child psychopathology over the last 15–20 years have been dependent on the structure and psychometric characteristics of the CBCL.) It should be quite easy to identify and summarize those studies that used a contrasted-groups design to identify those scales that are effective in making specific distinctions.

A review of CBCL citations would easily find carefully selected samples relevant to clinical practice and scale validity. These protocols could then be scored for 1991 dimensions and subsequent profile types to establish the proportion of each sample that is elevated on each dimension or obtains a specific classification for each instrument. For example, one investigation would be presented in tabular form by profile scales that would be represented by 11 columns (eight narrow-band, two broad-band, one summary) and samples that would be represented by individual rows. In this manner, one could determine not only if Anxious/Depressed is usually clinically elevated for students who receive solitary or combined anxiety and/or depression diagnoses, but that an Anxious/Depressed clinical elevation is infrequent in samples that are not characterized by either depression or anxiety. A review of this literature may also demonstrate which scales may be used to differentiate between conditions frequently addressed in the diagnostic process, as well as external correlates of these scales. (Apparently some of the best available published support for scale validity is confined to contrasted group analysis instead of continuous heterogeneous clinical samples and to the collection of nonindependent criteria from the same informant who completed the CBCL measure: see for example, Edelbrock & Costello, 1988; Weinstein, Noam, Grimes, Stone, & Schwab-Stone, 1990.)

4.13.2.4 Behavior Assessment System for Children

[American Guidance Service Inc., 4201 Woodland Road, Circle Pines, MN 55014-1796, USA]

The Behavior Assessment System for Children (BASC) differs from the three other systems presented in this chapter in that the entire system (Parent Rating Scales, PRS; Teacher Rating Scales, TRS; Self-report of Personality, SRP) was published at one time. (The BASC also includes a developmental history form and a classroom observation form, the Student Observation System). The BASC conveniently provides one integrated manual for all rating instruments (Reynolds & Kamphaus, 1992). Considering that these materials first became available in 1992 (with the advanced computer program first available in 1994), its application in the literature has been limited, although assessment applications continue to be developed. For example, the BASC Behavior Monitor for ADHD, brief parent and teacher forms intended for repeated use to demonstrate whether the behaviors of children already diagnosed as ADHD change as a result of treatment, became available in 1998.

In a manner similar to the Achenbach and the Conners' scales, the BASC ratings completed by parent, teacher, and youth are marked directly on self-scoring pamphlets or on one-page forms that allow the recording of responses for subsequent computer entry. Each of these forms is relatively brief (126–186 items) and can be completed in 10–30 minutes. PRS and TRS items are rated on a four-point frequency scale (never, sometimes, often, and almost always), while SRP items are rated as either true or false. Raw scale scores are easily obtained from the self-scoring form, although selecting and transferring scale and composite standard scores in the form of linear T scores from 77 pages of conversion tables appears to require significant effort and concentration. Computer scoring and interpretation greatly facilitate this process.

For all three informants, scales are provided that measure clinical dimensions and adaptive dimensions (positive, desirable). All items are placed on only one substantive scale following an iterative process in which item content, item to scale correlations, normative–clinical endorsement differences and factor structure determined scale structure. In addition, these scales are combined on the basis of their intercorrelations into broad-band measures or scale composites, Externalizing Problems, Internalizing Problems, and Adaptive Skills. The relative diagnostic utility of scales vs. composites remains to be demonstrated. Children of school age are evaluated by the use of parent (PRS) and teacher (TRS) forms designated for ages 6–11 or 12–18. Scale item composition differs by both informant and age group, although substantial similarity is demonstrated across age groups within each informant-specific form. The Self-report of Personality (SRP) is similarly divided into forms for ages 8–11 and 12–18. In contrast to the PRS and TRS that emphasize across-informant similarities, the SRP has been designed to complement parent and teacher reports as a measure focused upon emotions and self-perceptions rather than as reports of overt behaviors.

BASC forms are also notable for their incorporation of validity scales to estimate the accuracy of obtained standard scores as well as provision of a brief Critical Items set. (The BASC manual does not, however, explain the rationale for item selection or provide relevant item performance statistics for these critical items.) Three sets of norms are provided: gender-specific (including representative proportions of students receiving special education services), combined gender, and clinical.

The use of a combined gender normative sample to generate standard scores is the exception to general assessment practice, as most measures of adjustment and personality compare each student to same-gender norms. It would seem that such a procedure would further minimize the significance of disruptive behaviors in girls and internalizing symptoms in boys, as well as present boys as relatively lacking in adaptive competence when compared to girls (see BASC manual, Figure 11.2). One could easily calculate the effect of any cutting point, such as $T > 60$, on each BASC scale using both normative approaches within a sample of referred students. After students would be so identified, the accuracy of this classification could be established using information independent of BASC data.

In contrast to the BASC comprehensive normative sample, the sample used to generate clinical standard scores appears to both be limited in size (in some age/form samples less than 100 students) and restricted in composition. Yet test materials provide complete support for scoring results on clinical norms. Clinical norms are only routinely used for assessment measures that cannot be effectively applied within general population samples (e.g., a rating scale for severely disturbed hospitalized patients in which 99% of a regular population would obtain a summary score of 0). It is also difficult to define the parameters necessary to construct a "representative" clinical sample. Certainly TRS, PRS, and SRP samples of 30 or fewer children diagnosed as depressed or autistic would be inadequate for anything but initial exploration of scale or composite construct validity.

4.13.2.4.1 BASC Parent Rating Scales

PRS scale composites and associated narrow-band scales are Internalizing Problems (Anxiety, Depression, and Somatization), Externalization Problems (Hyperactivity, Aggression, and Conduct Problems), and Adaptive Skills (Adaptability (ages 6–11 only), Social Skills, and Leadership). Additional profiled scales include Atypicality, Withdrawal, and Attention Problems. The PRS also provides a Behavioral Symptoms Index, consisting of those clinical scales common to all age levels on both the PRS and TRS that load the highest on the first unrotated factor in a common-factor analysis. This combination of scales is presented in the manual as a measure of overall level of problem behavior. The BASC manual suggests that clinical scales should be considered of potential significance when $T > 60$, while adaptive scale scores should receive diagnostic attention when $T < 40$.

4.13.2.4.2 BASC Teacher Rating Scales

TRS scale composites and associated narrow-band scales include Internalizing Problems and Externalization Problems composites with the same narrow-band scales as for the PRS. The TRS Adaptive Skills composite includes the PRS scale components as well as a Study Skills scale that provides unique classroom observation (e.g., "Reads assigned chapters," "Studies with other students"). Both TRS forms provide a School Problems Composite that incorporates scales Attention Problems and Learning Problems ("Does not complete tests," "Makes careless errors"). In this manner the TRS provides 21 or 22 items that are unique to the classroom.

Both the PRS and TRS incorporate a "fake bad" (F) index to assess the possibility that a teacher or parent rated a child in an inordinately negative fashion. The F index includes 16–20 items per form that represent either maladaptive behaviors to which the respondent answered "Almost always" or adaptive behaviors to which the respondent answered "Never." These extreme scores (neither item nor scale statistics are provided in the manual) may represent either problem exaggeration or the presence of severe behavioral disturbance.

4.13.2.4.3 BASC Self-Report of Personality (SRP)

SRP scales and scale composites vary from both PRS and TRS dimensions. Narrow-band scales Attitude to School, Attitude to Teachers, and (only for ages 12–18) Sensation Seeking form the School Maladjustment Composite. Scales Atypicality, Locus of Control, Social Stress, Anxiety, and (only for ages 12–18) Somatization form the Clinical Maladjustment Composite. A Personal Adjustment Composite is formed by scales Relations with Parents, Interpersonal Relations, Self-Esteem, and Self-Reliance. Two other unassigned narrow-band scales are included: Depression and Sense of Inadequacy. An additional measure, the Emotional Symptoms Index (ESI) is, according to the BASC manual, the SRP's most global indicator of serious emotional disturbance, particularly internalized disorders. The ESI is composed of two scales from the Clinical Maladjustment composite (Social Stress and Anxiety), two scales from the Personal Adjustment composite (Interpersonal Relations and Self-Esteem), and the two clinical scales that do not appear on any SRP composite (Depression and Sense of Inadequacy). Interpretive guidelines presented in the BASC manual generally suggest that scores of 60–69T suggest an at-risk or mild/moderate range and scores above 69T a "clinical range" interpretation for clinical scales. Because the adaptive scales are worded and scored in the positive direction, low elevations are given interpretive significance, at comparable ranges of 31–40T and below 31T.

The SRP also provides three scales to measure the presence of response sets that are likely to compromise scale validity. As in the PRS and TRS, the SRP includes an F-Index composed of infrequent responses that may reflect symptom exaggeration ("Nobody likes me," "Nothing about me is right"). In addition, a 14-item L-Index has been incorporated to measure problem denial ("I always go to bed on time," "My parents are always right"). The third measure, V-Index, is not a scale but a small set of items that, when responded to in the True direction, are likely to reflect either lack of cooperation or inadequate comprehension ("I have never been in a car," "Television does not really exist").

4.13.2.4.4 BASC Monitor for ADHD

The BASC Monitor (Kamphaus & Reynolds, 1998) consists of brief parent and teacher forms that, along with the BASC Student Observation System and other variables defined by the clinician, provide a multimethod system designed to evaluate the effectiveness of treatments used with ADHD. The primary purpose is to demonstrate whether the behaviors of children already diagnosed as ADHD change as a result of treatment. These forms are intended for repeated use with the same child. Items are derived from 1992 PRS and TRS forms, other items collected during form development but not placed on a 1992 scale, as well as a few items written for this specific purpose that reflect *DSM-IV* diagnostic criteria. Norms were directly derived or extrapolated from BASC data and are organized into five age groups in order to be sensitive to age effects: 4–5, 6–7, 8–11, 12–14, and 15–18.

The Parent Monitor Ratings (PMR) consists of 46 items and the Teacher Monitor Ratings (TMR) consists of 47 items. All items are rated on the BASC four-choice frequency format of Never, Sometimes, Often, or Almost Always. Each form provides scales named Attention Problems, Hyperactivity, Internalizing Problems, and Adaptive Skills, and a listing of *DSM-IV* Items, some of which appear on other PRS and TRS scales, had been studied but not retained, or were written specifically to reflect *DSM* criteria. Item content was selected to be appropriate across the 4–18 years span, and some variation between PMR and TMR was allowed to reflect the unique opportunities for observation associated with each rater (e.g., TMR: "Bothers other children when working," PMR: "Fiddles with things while at meals").

4.13.2.4.5 Commentary

It is difficult for a newly published set of instruments to compete with those with a 20- to 30-year history of application. Certainly the BASC cannot draw upon an extensive research literature to demonstrate scale validity and to suggest appropriate clinical and research applications. The BASC family of instruments are attractive for several reasons, however, especially if all three ratings (parent-, teacher-, and self-report) are obtained for a student. Scale and composite distributions appear to be less skewed than many Achenbach and Conners' measures. Cluster analysis of the TRS normative sample, for example, resulted in seven clusters. In these clusters mean clinical scale *T* scores ranged from a low 40s to a high at or above 70, while mean adaptive scale *T* scores ranged from a low of 33 to a high of 60 (Kamphaus, Huberty, DiStefano, & Petoskey, 1997). The second reason, SRP *T* scores easily are obtained below 50*T*, in contrast to the YSR, and substantial item content is usually represented in *T* scores within the "clinical range." Another reason to consider these scales is that application of the BASC in school psychology settings in which ease of collection of both teacher and parent ratings is greater than in other settings would take advantage of the complementary nature of the SRP when the PRS and TRS are routinely collected. The final reason to consider the BASC is that the SRP scales appear especially attractive in the dimensions they generate, if parent and teacher ratings are available to document comorbid disruptive behavior phenomena. For example, it would be clinically meaningful in an adolescent described by parent and teacher as aggressive and conduct disordered if he would describe himself as seeing others as responsible for his problems (Locus of Control) and as focused on the experiences of thrill-seeking and excitement (Sensation Seeking).

As with any first manual, however, the psychologist will be left with many questions regarding application of BASC scales to the individual student. First, it is unclear from what source interpretive guidelines are derived, unless from scale item content. For example, elevation of SRP Sensation Seeking is presented to be associated with potential for alcohol and drug use or experimentation, while elevation of SRP Social Stress in young children with scores higher than 70*T* suggests children who "may turn inward in an unsuccessful attempt to cope with these tensions" (*BASC manual*, pp. 60–61). Perhaps these conclusions are not derived from scale correlates, but from an extrapolation of the phenomena associated with the clinical dimension measured by a given scale.

Although validity scales are provided, especially for SRP, the psychometric details of their construction and their performance in data presented in the manual are not provided. Does the L-Index correlate negatively with SRP clinical scales and positively with SRP adaptive scales? Were the clinical samples presented in the manual first screened by these scales to exclude potentially invalid protocols? The evidence of scale validity primarily takes the form of factor structure and correlations with other published measures. Readers of the manual will not find a series of case studies, nor are tabled and profiled mean scale values for a variety of referred samples presented in terms of proportion that exceed some value presented as clinically meaningful. In this regard, it is most interesting to contrast manual tables 12.28, 13.25, and 14.22 in that not one SRP clinical scale obtains a mean of at least $60T$, while only one adaptive scale score obtains a mean of $40T$ or less. Similar normal limits results were obtained for a relatively small sample of children in state custody due to abuse or neglect, although the L-Index was apparently not scored (Dalton, 1996).

A brief review of published studies using the PRS and TRS, in contrast, provides some encouraging evidence of scale validity. BASC parent and teacher scales demonstrated convergent validity with CBCL and TRF scales (Vaughn, Black, Hall, Hynd, & Riccio, 1995). PRS scales were found to demonstrate convergent validity in nonreferred kindergarten students with scales of the Social Skills Rating System for Children (Flanagan, Alfonso, Primavera, & Povall, 1996) and demonstrated similar validity in elementary school students at risk for conduct disorder with scales of the CBCL (Doyle, Ostrander, Skare, Crosby, & August, 1997). In a study of cognitive problem-solving, increasing PRF Hyperactivity Scale elevation was associated with more problem solutions with aggressive or noncompliant content as well as fewer reasons or consequences justifying the selection of the "best solution" (Bloomquist, August, Cohen, Doyle, & Everhart, 1997). Four TRS scales (Aggression, Conduct Problems, Depression, and Social Skills) significantly classified ADHD and nondisabled students, as well as ADHD students with and without a comorbid condition (Lett & Kamphaus, 1997). TRS Learning Problems correlated in referred elementary students with the Freedom from Distractibility factor, although no relation was obtained for the Attention Problems or Hyperactivity scales (Lowman, Schwanz, & Kamphaus, 1996). In addition, TRS Externalizing Problems correlated significantly with a peer rating dimension "aggressive–disruptive," while TRS Internalizing Problems correlated significantly with a peer rating dimension "sensitive–isolated" (Realmuto, August, Sieler, & Pessoa-Brandao, 1997). In a longitudinal study, teacher/parent composite measures of Hyperactivity/Attention Problems and Aggression/Conduct Problems were strongly intercorrelated and negatively related to adaptive functioning 3.5 years later (August, MacDonald, Realmuto, & Skare, 1996).

4.13.2.5 Personality Inventory for Children, 2nd Edition (PIC-2); Personality Inventory for Youth (PIY); Student Behavior Survey (SBS)

[Western Psychological Services, 12031 Wilshire Boulevard, Los Angeles, CA 90025-1251, USA]

Forty years ago two University of Minnesota psychologists began the development of a new inventory approach to the evaluation of children and adolescents. They assembled a 600-item administration booklet and named it the "Personality Inventory for Children. For use with children from six through adolescence." The directions stated that each item was to be answered as either "true" or "false" by the child's mother in order to describe both the child and family relationships. Professors Wirt and Broen accumulated administration booklet descriptive statements following an outline. To ensure comprehensive coverage of child behavior and adjustment, 50 items were sorted into 11 separate content areas: aggression, anxiety, asocial behavior, excitement, family relations, intellectual development, physical development, reality distortion, social skills, somatic concern, and withdrawal. To these 550 potential scale items, 50 items were added in an effort to strengthen or clarify the meaning of certain areas of concern. Following many of the general procedures employed in development of the Minnesota Multiphasic Personality Inventory, PIC scales were identified from this item pool over a span of 20 years.

The initial 1977 published profile included three validity scales, a general screening scale, and 12 measures of child ability and adjustment and family function developed through either empirical item selection techniques or through iterative content valid procedures. In 1981 the administration booklet was revised and items were sorted into one of four parts. Completion of part I (items 1–131) allowed the scoring of four broad-band factor-derived scales (Lachar, Gdowski, & Snyder, 1982). Completion of parts I and II (items 1–280) generated the entire clinical profile with "shortened scales" (Lachar, 1982), while parts I–III (420 items) allowed the scoring of the original length scales. The final 180 items of this booklet were eventually dropped from the administration booklet because they did not appear on any of the standard full-length profile scales.

From the beginning, the task of PIC scale and profile interpretation attributed relatively little importance to item content (except for the construction of a Critical Items list), but instead established external correlates and interpretive guidelines for individual profile scales (Lachar & Gdowski, 1979) and replicated profile patterns (Gdowski, Lachar, & Kline, 1985; Kline, Lachar, & Gdowski, 1987; LaCombe et al., 1991). A diagnostic procedure in which similarity coefficients are calculated between the individual PIC profile to be interpreted and the mean profiles of students receiving specific special education services has also been incorporated into profile scoring and interpretation software (Kline, Lachar, Grubber, & Boersma, 1994). Special effort has focused on determining that PIC scale validity is not restricted by a child's age, gender, or ethnicity status (Kline & Lachar, 1992; Kline et al., 1985).

The development efforts for the PIC-2 started in 1989 with the rewriting of the first 280 items of the PIC booklet into a self-report format for the PIY (Lachar & Gruber, 1993, 1995). Many dimensions were easily translated from the "my child" to the "I" format, although this process was either difficult or impossible for some dimensions. For example, accurate self-report of early developmental phenomena and severe developmental delay would be unlikely or inappropriate for students who can complete a comprehensive self-report inventory ("My child was difficult to toilet train," "My child can comb his/her own hair"). Such PIC items were replaced with other self-report statements likely to be used in validity scales or to supplement coverage of dimensions such as depression and defective reality testing (see PIY technical manual for an elaboration of this process). The PIY was developed with a subscale-within-scale structure that facilitates profile interpretation and has also incorporated a set of validity scales constructed from the responses of children and adolescents.

Development of the PIY facilitated concurrent critical review of the structure and content of PIC scales and the PIC profile. This review motivated substantial data collection using a PIC research edition administration booklet that allowed both the scoring of the PIC and the collection of data on revised and new inventory items. Data collected from application of this booklet have been subjected to considerable statistical analysis through which the PIC (now PIC-2) and PIY have achieved a great deal of similarity to facilitate comparison. The PIC validity scales, already a significant component of profile interpretation, have been improved in the PIC-2 and one consistent clinical scale and subscale construction methodology has been applied to the assessment of all revised clinical dimensions. In addition, a national normative sample has been collected concurrently with that for the third diagnostic component, a new teacher rating form, the Student Behavior Survey (SBS). Although these revisions have increased the focus on content validity in this family of parent, teacher, and self-report questionnaires, the 20-year tradition of deriving interpretive guidelines from the empirical relations between test measures and independent phenomena of adjustment and behaviour continues in the PIC-2 and SBS.

4.13.2.5.1 Personality Inventory for Children, 2nd Edition (PIC-2); Personality Inventory for Youth (PIY)

The PIC-2 and PIY profiles graph the linear *T* scores of three parallel validity scales and nine substantive clinical scales. PIC-2 norms are provided for students in grades K though 12 (a preschool version is under development), while PIY norms are available for students in grades 4 through 12. Clinical scales were constructed using an iterative process in which initial item placement based upon previous PIC scale placement and/or substantive item content was then empirically supported within item-to-scale correlation matrices based upon large clinical samples. Items retained in each final PIC-2 and PIY clinical scale demonstrated both statistical significance and the most substantial item-to-scale correlation among the nine potential scale placements. All other items, unless placed on an inventory validity scale or a critical item list, were dropped from the final version of each inventory. This process, in contrast to item selection through contrasted groups, placed an emphasis on item content and scale homogeneity.

The majority of PIY clinical scale items (86–100%, mean = 95%) appear on the identically named PIC-2 clinical scale, facilitating comparison of parent- and youth-report. The items of the PIY clinical scales are placed on only one scale and one subscale. Of the 264 items that comprise the nine PIC-2 clinical scales, only 16 (6.1%) appear on two scales. Each clinical scale is also divided into two or three nonoverlapping subscales. Guided by a series of item factor analyses, these subscales consist of item subsets that are more homogeneous than their associated total scales. Clinical and validity scale content remains the same across child age or gender, allowing expected age- and gender-related variance to appear. (For example, greater elevation on the Impulsivity and Distractibility scale will be found for boys in comparison to girls and for younger children in comparison to older children.) PIY clinical scales become interpretable at 60*T*, and subscales usually at 65*T*. (Analyses of PIC-2 scale standard scores suggest comparable guidelines.) Table 3 presents the scale/subscale structure, representative items, and internal consistency estimates of the PIC-2 parent-report and PIY self-report clinical scales.

Table 3 demonstrates that PIC-2 and PIY item content varies from the description of commonly occurring difficulties to statements suggestive of severe psychopathology. It should be noted that many PIC-2 and PIY subscales incorporate more descriptors than the full scales found in the other three families of objective questionnaires.

The PIY and PIC-2 both incorporate a screening or short assessment procedure. The first 80 items of the PIY comprise a 32-item screening scale chosen to provide an optimal identification of those regular education students who—when administered the full PIY—produced clinically significant results. These items also include three "scan items" for each scale. Scan items were selected in such a manner so that individuals who endorse two or more of each set of three items would be those with a high probability of scoring $> 59T$ on the corresponding clinical scale. Shortened versions of three validity scales can also be derived from these items.

The PIC-2 provides a short form to measure change in clinical status associated with therapeutic intervention. Although PIC scales may have demonstrated such sensitivity to change (see therapeutic case example in Lachar & Kline, 1994), a brief form tailored specifically for this purpose was constructed. Selected items were (i) written in the present tense, (ii) frequently endorsed in the context of clinical assessment, and (iii) described clinical phenomena often the focus of short-term intervention. Using these guidelines, the 12 most favourable items from each of eight PIC-2 clinical scales were selected. (Cognitive Impairment was excluded due to historical components, lack of appropriate therapeutic focus, and the global/stable nature of most descriptions on this dimension.) These 96 inventory statements have been placed at the beginning of the 275-item PIC-2 booklet to serve as both a short form and a method of efficient re-evaluation of a child following short-term intervention. These 96 items are also available in a self-scoring format. It is intended for these scale scores to be graphed on the same profile at baseline and at appropriate interim and post-treatment intervals to demonstrate both dimensions of change and stability.

The initial concurrent validity of these shortened scales was established through correlation of these scale scores with clinician ratings, teacher descriptions, and self-report descriptions. These data were drawn from an ongoing clinical project in which the PIY, SBS, clinician ratings, diagnoses, and individually administered psychometric results are being collected to some degree with over 1000 PIC-2 assessments. Even though an exploratory analysis, some care was taken in the selection of these correlates. Each obtained scale descriptor was placed on only the one scale with which it received the largest correlation, all being at least significant at $p < 0.01$. Table 4 summarizes the number of ratings identified in this manner from each source (clinician, teacher, and student) and provides three examples from each rating source for each of these eight scales. Correlations between these shortened scales and their full-length versions are also presented.

Table 4 demonstrates that these brief scales correlated substantially with full-length versions and obtained independent correlates from nonparent observers that matched expressed scale content and diagnostic intent. Clinicians provided the greatest support for ADH, DLQ, and DIS, focusing on problems of disruptive and noncompliant behavior and intense and dysphoric affect that often form the basis of clinical referral. These analyses demonstrate that ADH, as previously demonstrated for the PIC Hyperactivity scale (Lachar & Gdowski, 1979), assesses those behaviors most related to problems in classroom adjustment. In addition, observations obtained directly from the student under study provide those internal and subjective judgments that demonstrate the clinical value of PIC-2 dimensions which do not receive robust correlates from clinicians or teachers.

PIY and PIC-2 profiles incorporate three validity scales. The Inconsistency scale (INC) evaluates the likelihood that responses to items are random or reflect in some manner inadequate comprehension of inventory statements or compliance with test instructions. The Defensiveness scale (DEF) identifies profiles likely to demonstrate the effect of minimization or denial of current problems. The third validity scale, Dissimulation (FB), identifies profiles that may result from either exaggeration of current problems or a malingered pattern of atypical or infrequent symptoms.

PIY and PIC-2 Inconsistency scales measure semantic inconsistency through the classification of response to 35 pairs of highly correlated items drawn from all nine clinical scales (for example, "I have many friends/I have very few friends"; "My child has a lot of talent/My child has no special talents"). For each item pair, two response combinations are consistent and two are inconsistent. Each inconsistent pair

Table 3 PIC-2 and PIY Clinical Scale and Subscale Composition.

Cognitive Impairment PIC-2: 39 items, alpha = .881
PIY: 20 items, alpha = .740
Items in common: 20 (only 1 on PIC/2 COG3)

PIC-2 Subscales:
COG1/Inadequate Abilities (13 items, alpha = .792)
My child is rather absent-minded.
COG2/Poor Achievement (13 items, alpha = .785)
Reading has been a problem for my child.
COG3/Developmental Delay (13 items, alpha = .799)
My child could eat with a fork before age four years.

PIY Subscales:
COG1/Poor Achievement and Memory (8 items, alpha = .649)
School has been easy for me.
COG2/Inadequate Abilities (8 items, alpha = .673)
Other people think that I am talented.
COG3/Learning Problems (4 items, alpha = .441)
I have been held back a year in school.

Impulsivity and Distractibility PIC-2: 27 items, alpha = .921
PIY: 17 items, alpha = .773
Items in common: 17

PIC-2 Subscales:
ADH1/Disruptive Behavior (21 items, alpha = .917)
My child jumps from one activity to another.
ADH2/Fearlessness (6 items, alpha = .693)
My child will do anything on a dare.

PIY Subscales:
ADH1/Brashness (4 items, alpha = .535)
I like to show off.
ADH2/Distractibility/Overactivity (8 items, alpha = .613)
I cannot keep my attention on anything.
ADH3/Impulsivity (5 items, alpha = .543)
I often act without thinking.

Delinquency PIC-2: 47 items, alpha = .957
PIY: 42 items, alpha = .923
Items in common: 39

PIC-2 Subscales:
DLQ1/Antisocial Behavior (13 items, alpha = .881)
My child has been in trouble with the police.
DLQ2/Dyscontrol (17 items, alpha = .921)
When my child gets mad, watch out!
DLQ3/Noncompliance (17 items, alpha = .927)
My child often disobeys me.

PIY Subscales:
DLQ1/Antisocial Behavior (15 items, alpha = .831)
I have run away from home.
DLQ2/Dyscontrol (16 items, alpha = .839)
What people say often makes me angry.
DLQ3/Noncompliance (11 items, alpha = .828)
I tend to see how much I can get away with.

Family Dysfunction PIC-2: 25 items, alpha = .882
PIY: 29 items, alpha = .869
Items in common: 25

PIC-2 Subscales:
FAM1/Conflict Among Members (15 items, alpha = .847)
Out family argues a lot at dinner time.
FAM2/Parent Maladjustment (10 items, alpha = .781)
One of the child's parents drinks too much alcohol

Table 3 (continued).

PIY Subscales:
FAM1/Parent–Child Conflict (9 items, alpha = .817)
I am unhappy about my home life.
FAM2/Parent Maladjustment (13 items, alpha = .738)
My parents often argue.
FAM3/Marital Discord (7 items, alpha = .701)
My parents are now divorced or living apart.

Reality Distortion PIC-2: 29 items, alpha = .898
PIY: 22 items, alpha = .831
Items in common: 20

PIC-2 Subscales:
RLT1/Developmental Deviation (14 items, alpha = .842)
My child does not understand other people.
RLT2/Hallucinations and Delusions (15 items, alpha = .817)
My child sometimes sees things that are not there.

PIY Subscales:
RLT1/Feelings of Alienation (11 items, alpha = .768)
I am different from most kids.
RLT2/Hallucinations and Delusions (11 items, alpha = .709)
People secretly control my thoughts.

Somatic Concern PIC-2: 28 items, alpha = .829
PIY: 27 items, alpha = .853
Items in common: 24

PIC-2 Subscales:
SOM1/Psychosomatic Preoccupation (17 items, alpha = .793)
My child seems tired most of the time.
SOM2/Muscular Tension and Anxiety (11 items, alpha = .675)
Recently my child has complained of chest pains.

PIY Subscales:
SOM1/Psychosomatic Syndrome (9 items, alpha = .730)
I often have headaches.
SOM2/Muscular Tension and Anxiety (10 items, alpha = .740)
At times I have trouble breathing.
SOM3/Preoccupation with Disease (8 items, alpha = .596)
I am worried about disease.

Psychological Discomfort PIC-2: 39 items, alpha = .909
PIY: 32 items, alpha = .864
Items in common: 31

PIC-2 Subscales:
DIS1/Fear and Worry (13 items, alpha = .728)
My child is often afraid of little things.
DIS2/Depression (18 items, alpha = .881)
My child tends to feel sorry for himself/herself.
DIS3/Sleep Disturbance/Preoccupation with Death (8 items, alpha = .770)
My child's sleep is calm and restful.

PIY Subscales:
DIS1/Fear and Worry (15 items, alpha = .779)
I worry about things that adults worry about.
DIS2/Depression (11 items, alpha = .730)
The future looks good to me.
DIS3/Sleep Disturbance (6 items, alpha = .703)
I often get up at night.

Social Withdrawal PIC-2: 19 items, alpha = .796
PIY: 18 items, alpha = .800
Items in common: 18

Table 3 (continued).

PIC-2 Subscales:
WDL1/Social Introversion (11 items, alpha = .781)
  My child worries about talking to others.
WDL2/Isolation (8 items, alpha = .656)
  My child often stays in his/her room for hours.

PIY Subscales:
WDL1/Social Introversion (10 items, alpha = .781)
  Shyness is my biggest problem.
WDL2/Isolation (8 items, alpha = .591)
  I keep my thoughts to myself.

Social Skill Deficits PIC-2: 28 items, alpha = .915
PIY: 24 items, alpha = .855
Items in common: 23
PIC-2 Subscales:
SSK1/Limited Peer Status (13 items, alpha = .853)
  My child often brings friends home.
SSK2/Conflict with Peers (15 items, alpha = .888)
  Other children often get mad at my child.

PIY Subscales:
SSK1/Limited Peer Status (13 items, alpha = .788)
  I am sure of myself in a group.
SSK2/Conflict with Peers (11 items, alpha = .804)
  Other kids make fun of my ideas.

Note: coefficient alphas based upon 1178 PIY and 901 PIC-2 protocols obtained in the context of clinical evaluation.

identified in a given protocol contributes one point to the INC raw score. Application of a cutting raw score of > 12 resulted in correct identification of 90–95% of clinical protocols and 92–96% of a random sample. The DEF is an expanded version of the PIC Lie scale. DEF items represent denials of common problems ("Sometimes I put off doing a chore. False"; "My child almost never argues. True") and attributions of improbable positive adjustment ("My child always does his/her homework on time. True"; "I am almost always on time and remember what I am supposed to do. True"). DEF elevations above 59*T*, even in hospitalized psychiatric patients, result in profiles that either minimize current problems or consistently deny the presence of most or all problems in adjustment.

The third validity scale, Dissimulation (FB), was empirically constructed through item analysis comparing clinical protocols and two sets of protocols completed by nonreferred regular education students or their mothers. First the PIY or PIC-2 was completed with directions to provide an accurate description, then a second questionnaire was completed as if the student was in need of mental health counseling or hospitalization. Selected items in the scored direction were very infrequent in the accurate normal (PIY, 11%; PIC-2, 4%) and clinical (PIY, 18%; PIC-2, 15%) condition, while characteristic (PIY, 83%; PIC-2, 55%) of the "fake bad" or dissimulated condition. The pattern of these three scales readily identifies profiles in which caution must be applied to their interpretation. Table 5 presents PIC-2 and PIY profile scores from three hospitalized 12-year-old adolescents.

The evaluation of Case A resulted in PIC-2 and PIY validity scale results which did not suggest that the accuracy of these profiles had been compromised in any systematic manner. It is important to observe that both profiles present clinically elevated scale scores. First consider similarities in scale and subscale pattern and scale and subscale clinical elevations (e.g., apparent disagreement for COG3 represents the reality that PIC-2 COG3 consists of parent report of developmental delay, while PIY COG3 represents learning problems—a dimension much more similar to PIC-2 COG2). Case A is a 12-year-old in his fifth psychiatric hospitalization who had been placed in a self-contained special education classroom for behavioral maladjustment. He carries diagnoses of ADHD combined type, Oppositional Defiant Disorder, and Conduct Disorder. His behavior at home and in the hospital demonstrated serious behavioral dyscontrol. He had been noncompliant in taking psychotropic medication to improve his emotional and behavioral control. He had threatened to kill himself (see

Table 4 Correlates of PIC-2 Brief Clinical Scales.

Impulsivity and Distractibility (ADH12: .96[a])

Clinician Ratings: total = 14
Hyperactive, overactive
Restless
Frequently frustrated

Teacher Ratings: total = 34
Disobeys class or school rules
Impulsive, acts without thinking
Misbehaves unless closely supervised

Student Ratings: total = 9
Brags about being sent to the principal
School has sent notes home about bad behavior
Likes to show off

Delinquency (DLQ12: .93)

Clinician Ratings: total = 44
Argues, Oppositional
Disobedient to parents
Poorly modulated anger

Teacher Ratings: total = 11
Does not demonstrate polite behavior
Blames others for his/her problems
Becomes upset for little or no reason

Student Ratings: total = 24
Gives parents a lot of trouble
Sometimes swear at parents
Ran away from home

Family Dysfunction (FAM12: .93)

Clinician Ratings: total = 6
Conflict between parents
Parent divorce/separation
Emotionally abused

Teacher Ratings: total = 6
Uses alcohol or drugs
Strikes or pushes school personnel
Preoccupied with sex

Student Ratings: total = 18
Family does not enjoy being with each other more than other families
A lot of tension in the home
Parents often argue

Reality Distortion (RLT12: .95)

Clinician Ratings: total = 3
Auditory hallucinations
Inappropriate emotion, affect
Delusions, paranoia

Teacher Ratings: total = 0

Student Ratings: total = 13
Don't get along with others most of the time
Need a lot of help from others
Do strange or unusual things

Somatic Concern (SOM12: .92)

Clinician Ratings: total = 6
Excessive sleeping
Sexually abused
Continually tired, listless

Table 4 (continued).

Teacher Ratings: total = 0

Student Ratings: total = 33
Often get very tired
At times have trouble breathing
Don't have as much energy as most other kids

Psychological Discomfort (DIS12: .93)

Clinician Ratings: total = 22
Depressed, sad, unhappy
Moodiness
Inadequate self-esteem

Teacher Ratings: total = 4
Appears sad or unhappy
Doesn't take successes and failures in stride
Worries about little things

Student Ratings: total = 25
Shy with kids my own age
Not often in a good mood
Often afraid of little things

Social Withdrawal (WDL12: .96)

Clinician Ratings: total = 4
Withdrawn
Shy
Uncommunicative, seldom talks

Teacher Ratings: total = 2
Pessimistic about the future
Overcritical of himself/herself

Student Ratings: total = 12
Shyness is my biggest problem
Hardly ever talk
Stay in the house for days at a time

Social Skill Deficits (SSK12: .96)

Clinician Ratings: total = 5
Teased by peers
Isolated, few or no friends
Attends self-contained special education class

Teacher Ratings: total = 17
Does not seem to have fun
Avoids social interaction in class
Unaware of the feelings of others

Student Ratings: total = 28
Often rejected by other kids
Have very few friends
Not very popular with other kids

[a] Indicates correlation between total and 12-item version of PIC-2 clinical scale in a sample of 905 referred students. Note text for explanation of correlate selection procedure.

DIS3 scores) and had assaulted his mother who he said did not want him at home (see PIY FAM1 and FAM2). This patient attempted to escape from the hospital and required multiple time-outs and seclusions to control rages, threats, and aggressive and inappropriate behavior (see DLQ2). Off medication, A demonstrated an attention span of less that 15 minutes (see ADH values). He had a history of impulsive and disruptive behavior, fighting with peers, noncompliance with adults, verbal and physical aggression, and running away from home (elevated DLQ values for PIY and PIC-2).

Case B, in contrast to Case A, documents considerable parent/child disagreement. The

only clear agreement as to problem area is in academic achievement (PIC-2 COG2, PIY COG3). History and psychometric assessment document retention in grade, special class placement, and achievement substantially below assessed ability. Clearly the PIC-2 most accurately describes a 12-year-old male who demonstrates multiple handicaps. The elevation of the PIY DEF scale ($T = 64$) is the most likely explanation for a PIY profile that is essentially within normal limits. Indeed, review of the medical record details this patient's repeated denial and minimizing of his problems during this hospitalization in an attempt to facilitate his early discharge from treatment. This child's psychiatric history was secondary to a traumatic motor vehicle accident. He felt lonely and scared, he frequently cried, sobbed, shook, avoided others, and was preoccupied with excessive worries (DIS, WDL). He externalized his problems (DLQ) and had difficulties with peers and had little insight into his role in these conflicts (SSK2). This pattern of youth defensiveness is fairly common in inpatient settings.

Case C is quite unusual in that the mother-completed PIC-2 is essentially within normal limits, with the exception of FAM1, FAM2, and DIS3 obtaining some elevation. This normal-limits profile is quite unusual in light of the fact that the mother referred her 12-year-old daughter for this hospitalization. C presented with suicidal ideation, low self-esteem, depression, crying spells, poor appetite, and associated weight loss (DIS, WDL2). She actively demonstrated somatic concern and somatic symptoms in response to conflict during this hospitalization (SOM) and said that she would not talk about her problems with her mother, because she was afraid that such discussion would distress her mother who was under psychiatric care (PIC-2 FAM2). Clinicians were sufficiently concerned with C's internalizing problems to assign discharge diagnoses of Generalized Anxiety Disorder and Depressive Disorder NOS and to prescribe antidepressant medication. Why was C's mother more defensive in describing her daughter's problems than C was herself? It was clearly documented in the medical record that C's mother was concerned that, because of her and C's psychiatric problems, she would be seen as an inadequate mother and consequently would lose custody of her child to another adult family member.

4.13.2.5.2 Student Behavior Survey

The Student Behavior Survey (SBS) differs from the other teacher rating scales described in this chapter in that no particular effort was made to develop the SBS into a parallel teacher version of the PIC-2 and PIY. Indeed, the development of SBS items consisted of several iterations in which the authors focused on content appropriate to teacher observation. SBS items and their rating options appear on a self-scoring form. These items are sorted into content meaningful dimensions under 11 scale headings rather than presented in random order. The resulting items demonstrate a school focus in that 58 of 102 items specifically refer to in-class or in-school behaviors and judgments that can only be made by school staff (Wingenfeld, Lachar, Gruber, & Kline, 1998). The SBS consists of 102 items profiled on to 14 scales that assess student academic status and work habits, social skills, parental participation in the educational process, and problems such as aggressive or atypical behavior and emotional stress. Norms that generate linear *T* scores are gender-specific and divided into two age groups: 5–11 and 12–18 years.

The SBS consists of three sections (Lachar et al., 1999). In the first section the teacher circles one rating out of five (Deficient, Below Average, Average, Above Average, Superior) for eight areas of achievement such as reading comprehension and mathematics that are summed for an estimate of current academic performance. The remaining SBS items are rated on a four-point frequency scale: Never, Seldom, Sometimes, and Usually. The next two scales consist of positively worded descriptions of student adaptive behaviors. Academic Habits (13 items; "Completes class assignments"; "Follows the teacher's directions") and Social Skills (eight items: "Helps other students"; "Participates in class activities") scales document positive behaviors. Ratings of parents are very school-specific in that the teacher is asked to judge the degree to which parents support the student's educational program (six items: "Parent(s) encourage achievement"; "Parent(s) meet with school staff when asked").

The seven Problems in Adjustment scales consist of negatively worded items organized into Health Concerns (six items: "Complains of headaches"; "Talks about being sick"); Emotional Distress (15 items: "Appears sad or unhappy"; "Worries about little things"); Unusual Behavior (seven items: "Seems lost or disoriented"; "Says strange or bizarre things"); Social Problems (12 items: "Criticized by other students"; "Avoids social interaction in class"); Verbal Aggression (seven items: "Insults other students"; "Teases or taunts other students"); Physical Aggression (five items: "Destroys property when angry"; "Starts fights with other students"); and Behavior Problems (15 items: "Disrupts class by misbehaving"; "Talks excessively"). In initial samples of 1173 regular education students and 601 students referred for evaluation or receiving special education services in grades K through 12, 99 of 102 items significantly ($p < 0.001$) separated these two samples. All items demonstrated that they had been placed on the scale with which each obtained the largest correlation. Scale scores of regular education and referred students obtained meaningful three-factor solutions.

Additional effort (Pisecco et al., 1998) resulted in three additional, 16-item nonoverlapping scales consisting of SBS items first nominated as fitting *DSM-IV* diagnoses of ADHD (combined type), Oppositional Defiant Disorder, and Conduct Disorder. Item-to-scale correlations and a three-factor solution of these 48 SBS items empirically supported the placement of these scale items.

4.13.2.5.3 Commentary

The revision of the PIC, the addition of a teacher rating scale, and the collection of a national representative normative sample for each have gone a long way to respond to the concerns raised by reviewers regarding the PIC's age (Kamphaus & Frick, 1996; Knoff, 1989; Merrell, 1994). The evaluations of the SBS and PIC-2 manuals and the review of their subsequent demonstrated ability to evaluate emotional adjustment at baseline and to quantify response to intervention will appear well into the twenty-first century.

The emphasis on evaluating response accuracy using validity scales and the empirical determination of interpretive guidelines continues to characterize these measures. Many psychologists unconvinced of the importance of these concepts may not value their contributions to assessment. Although the PIC has been reduced from 420 to 275 items, into which a set of subscales and a brief form have been incorporated, some clinicians may still judge the length of these questionnaires to be problematic. Although this chapter's author is obviously biased against such a position, it is certain that the breadth and depth of a measure's content establishes the potential boundaries for its utility. Even the 270 items of the PIY are easily completed in less than 45 minutes by children as young as students in the fourth grade. Efficiency has been improved by rejecting any item not actively used in the interpretive process as well as providing computer software for scoring and interpretation.

As either "new" or "improved" measures, the approximately 400 PIC-relevant publications (bibliography available from this author) at best now suggest diagnostic potential for these forms on the dimensions that retain the greatest similarity from original to revised formats. A great deal of effort will be necessary to establish the diagnostic utility of the new and revised forms to achieve the standards of the original inventory (Lachar & Kline, 1994). Such efforts have begun. For example, matched samples of adolescents with discharge diagnoses of either Conduct Disorder or Major Depression were correctly classified by PIY subscales in 83% of cases (Lachar, Harper, Green, Morgan, & Wheeler, 1996).

4.13.3 CONCLUSIONS

Clinician interest in applying objective questionnaires in the evaluation of children and adolescents continues to grow. These measures are efficiently obtained, easily scored, and at least appear to be relatively easy to interpret (although a sophisticated knowledge of both developmental psychopathology and psychometrics is clearly a prerequisite). The routine application of such measures in clinics, hospitals, and private practices will continue to be a growing trend. This chapter documents that a number of quality measures are currently available to meet this need. Clinicians should review each set of measures to select the specific family of instruments best suited for them to be applied as a routine procedure, or the specific instruments to be applied to a specific clinical activity.

Routine collection of information that is both multidimensional and multisource will influence future research and clinical practice. Efforts to document the effect of comorbid conditions and to establish interpretive guidelines for individual profiles and sets of profiles will continue. Interpretive handbooks, similar to those available for popular adult personality inventories, will be developed to support training and clinical applications. Projects will identify research designs in which the meaning of scale values and profile patterns can be established through the analysis of independent criteria. Given the infrequency of studies designed to evaluate tests, as compared to studies that use tests to evaluate clinical phenomena, efforts will be made to identify and collect substantial data that will allow such analyses. Indeed, the concurrent application of parent, teacher, youth, and clinician forms, as demonstrated in Table 4, will allow the establishment of external correlates and the determination of scale standard score interpretive ranges.

Studies will routinely investigate the relative efficacy of informant sources (parent, teacher, and youth) to support a given diagnostic decision, as well as compare the instruments across these four families. Some early efforts include Pearson and Lachar's (1994) comparison of CBCL and PIC scales in their ability to predict the standard scores of the Vineland Adaptive Behavior Scale, and the comparison of BASC and CBCL forms in identifying students with ADHD and in differentiating between ADHD types (Ostrander, Weinfurt, Yarnold, & August, in press; Vaughn et al., 1997). The former study established the relative value of the BASC PRS Attention Problem Scale for identifying students likely to demonstrate nonspecific ADHD, although both measures demonstrated limited ability to identify ADHD subtype. In the second study, both BASC parent and teacher scales demonstrated significant superiority over the CBCL and TRF in accurately classifying ADHD type.

The routine use of these measures will expand to repeated assessment paradigms. The interest in measuring treatment effectiveness as a clinical as well as a research priority will make a meaningful contribution to identifying optimal treatment strategies as well as assigning specific treatment options for the individual case. These trends will facilitate retrospective "file drawer" study within clinical settings and expand the investigation of clinically referred youth.

4.14.1 INTRODUCTION

Objective personality tests form a standard part of most applied psychologists' toolboxes when it comes to measuring personality. In contrast to projective techniques and to subjective approaches to personality assessment, objective personality questionnaires are made up of relatively unambiguous stimuli or items; offer the respondent relatively restricted response options; and present a scoring scheme that involves few, if any, scoring judgments, resulting in high scoring reliability (Wiggins, 1973). Most objective personality assessment instruments used by clinicians and researchers employ a self-report format. In contemporary psychology, the Minnesota Multiphasic Personality Inventory (MMPI) and the MMPI-2 are the most widely used personality assessment instruments in both clinical and research settings (Butcher and Rouse, 1996). The next most popular instruments used to assess personality, the Rorschach and the Thematic Apperception Test, are projective (not objective), but each still requires the clinician to obtain self-reported behavior. In essence, the clinician is dependent on the client's ability and willingness to make accurate self-reports when assessing personality with standardized instruments. It is, therefore, important to determine whether adults being assessed can competently reveal information about their personalities through self-report instruments. In order to address this question, the client's intelligence and insight in sharing self-information and the success of personality tests for eliciting self-information that can be externally verified need to be considered. We will examine each of these considerations below.

4.14.1.1 Intelligence and Insight

The existing literature on intelligence and personality is largely focused on the predictive relationship between the two constructs. However, clinicians are generally not concerned about the ability of a personality profile to predict an intelligence quotient or vice versa. Instead, most are concerned with the more basic question of how intellectual functioning impacts the ability of a client to self-disclose on an objective personality test. No literature exists which directly addresses the issue of the relationship between a client's level of intelligence and his or her ability to competently reveal information about personality through a self-report instrument.

Objective personality measures leave the issue of the client's intellectual functioning in the hands of the clinician. None of the widely used personality assessment instruments require a pre-screening for normal or above normal intelligence. However, most self-report personality instruments require that the examinee have a minimum reading level competency (often expressed as a minimum grade level). Thus, a minimum level of school achievement is implicit in the validity of a client's score, and it follows that the clinician should use care when administering a self-report instrument to a client with known or suspected intellectual impairment. It is also essential for the clinician to be aware of the educational range of the standardization sample for any self-report measure, and to use caution when interpreting protocols from clients who fall outside of that range.

The clinician needs to be aware of a client's intellectual functioning as it may influence the client's ability to provide information about his or her personality on a self-report measure. If a client appears to be low in intellectual functioning, then the results of self-report measures should be interpreted with caution and perhaps supplemented with reports from other sources.

While the capacity for insight cannot readily be extrapolated from an intelligence quotient in a linear fashion, insight into one's problems might be discernible from the personality profile itself. As Butcher and Rouse (1996) note in their recent review of personality research, several of the widely used objective personality measures have attitudinal measures that aid the clinician in evaluating the client's disclosure capability. Crookes and Buckley (1976) found a relationship between the Eysenck Personality Inventory Lie (L) scale score and diagnosis among both psychiatric inpatients and outpatients. They found that high L scale scores were positively related to diagnosis of disorders associated with low insight. They concluded that the L score (a validity indicator found on several objective personality instruments) is highly related to a person's awareness of his or her behavior. Moreover, this finding is in agreement with the interpretive guidelines for the MMPI-2 L scale, which suggests the general utility of this measure at appraising a client's self-awareness.

The quality of insight that a client brings to the assessment situation may greatly influence the validity of the assessment. Some instruments are designed to assess clients through behavioral items that require low insight or self-observation. These items are specifically selected because of their ability to predict relevant criteria and may appear at face value totally unrelated to the particular aspects of personality functioning intended to be predicted. This highlights one advantage of using objective personality measures in clinical settings: clients who may yield poor information during a clinical interview that requires self-evaluation and/or introspection may be fully capable of providing valuable clinical information when a personality instrument comprising empirically selected items is employed.

4.14.1.2 Veridicality of Self-report

Aside from the issues of intellectual functioning and insight the utility of self-report measures can be assessed by examining their success at corroborating independent facts about a client. For example, in an early study of the MMPI, Payne and Wiggins (1972) examined the relationship between content-based profiles and external descriptors of a large group of psychiatric inpatients. Interpretation of content-based profiles is based on combinations of "obvious" test items which correspond to traditional self-report instruments (e.g., "I am a high-strung person"). That is, the client endorses the item as a means of directly relaying information about him- or herself. The authors found that the patients' self-reported MMPI profiles matched quite well with interview report and external observation.

In a similar vein, Koss and Butcher (1973) found that psychiatric inpatients identified (through their observed behavior and presenting symptoms) as belonging to one of six operationally defined crisis situations could be discriminated from one another on the basis of their endorsed MMPI content. The authors interpreted their results as providing evidence for the competence and willingness of adults in clinical settings to reflect information accurately about their personality and psychological functioning through self-report test items. Similar evidence of a positive relationship between self-reported personality measures and external criteria has been found for certain scales from the California Psychological Inventory (CPI; e.g., Hindelang, 1972), the Millon Clinical Multiaxial Inventory (MCMI; e.g., Jaffe and Archer, 1987), and the Basic Personality Inventory (BPI; Holden, Fekken, Reddon, Helmes, & Jackson, 1988), to name three.

Although the research literature shows that people can competently disclose information about their personalities through standardized, objective, self-report measures, some individuals, however, may not be motivated to cooperate in their psychological assessment. That is, some respondents, because of a need or motivation to present themselves in a particular way, do not respond in a truthful, open manner. The most common examples of individuals being motivated to appear different from the way they actually are in today's assessment settings are applicants for employment, parents involved in custody disputes, and other individuals being evaluated as part of a court case. A self-report assessment instrument must contain an effective means of identifying respondents who are dissimulating. Perhaps the most common way of detecting whether people are not motivated to report accurately about themselves is via validity scales or control scales. In some assessment situations the validity scales provide the most important and useful information about the client. A self-report personality measure without effective validity scales is too limited to operate across a broad range of assessment situations. Furthermore, tests that possess validity indicators, such as the L scale on the MMPI/MMPI-2, offer the clinician information regarding both the client's willingness to cooperate with the assessment and his or her level of insight. These points argue in favor of the continued use of standardized, objective self-report measures in the assessment of personality in clinical settings.

4.14.1.3 Personality Stability

One of the assumptions of objective personality assessment is that the personality characteristic being measured is stable. Various major studies have come to the conclusion that personality changes little in adulthood, particularly after age 30 (Conley, 1985; Finn, 1986; McCrae & Costa, 1990; Schuerger, Zarrella, & Hotz, 1989). Typical levels of stability on personality tests are in the 0.5–0.7 range. This generalization bears some comment.

4.14.1.3.1 Definitions

What exactly is meant by stable responding? On an objective personality questionnaire, a set of responses that are consistent over time may be defined in at least three ways: (i) as an identical scale score, (ii) as a set of identical item responses, or (iii) as a scale score that signifies the same relative standing on the personality characteristic.

Conclusions about the stability of personality are most commonly based on scale scores. That is, the stability of personality estimates result from comparing scale scores obtained at two points in time. Presumably the same scale score could result even if the test respondent endorsed somewhat different subsets of items. The consistency of responses to individual test items has been studied as a meaningful individual differences variable and as an index for establishing the interpretability of individual response protocols. Item response consistency has not been examined as a definition of longitudinal personality stability *per se*.

Many researchers have focused on changes in average scale scores. Their goal is to understand normative changes in personality. On the other hand, some researchers examine personality stability by correlating scale scores. Thus, when coefficients of personality stability are reported to be in the 0.5–0.7 range, this should be understood to be a statement about relative, and not absolute, scale score stability.

4.14.1.3.2 Influences on personality stability

Although the typical stability of personality scale scores is quite high, there are nonetheless particular variables that affect score stability in predictable ways. The first consideration is the influence of instrument characteristics. Specifically, the average number of items per scale and the homogeneity of the scales are the important predictors of scale score stability (Finn, 1986; Schuerger et al., 1989). Variance associated with specific instruments (e.g., the MMPI vs. the Sixteen Personality Factor Test [16PF]) apparently does not contribute to greater personality stability beyond the effects of scale length and homogeneity (Schuerger et al., 1989). Such findings underscore the need for test users to select reliable measures, particularly if test data are intended to evaluate long-term personality change.

Second, estimates of personality stability are affected by the length of the retest interval. Not surprisingly, personality appears to more stable over short intervals than long ones. In particular, score stability drops over the first year before it levels off (Schuerger et al., 1989; Windle, 1954) and then stays stable at the same level for very long periods of time (McCrae & Costa, 1990).

One simple reason for relatively high short-term personality stability may be that people remember and repeat their responses to the items on a questionnaire. Lumsden (1977), however, proposed a substantive rather than a methodological explanation. He argued that particular personality characteristics "swell" into prominence over the short term and then fade again. For a student entering college, for example, "independence" may become a salient dimension and hence, self-reports on this dimension are likely to have exaggerated consistency over the (short) time period when "independence" is prominent.

A third influence on personality stability has to do with the operationalization of personality. Most objective personality questionnaires are intended to measure traits that are by definition stable and enduring. The construction of such questionnaires favors selection of items that will yield stable scores. In addition, the overall instructions as well as the wording of specific items prompt people to make broad generalizations about themselves and to downplay variations. Thus, personality may appear to be stable because the constructs of personality are explicitly conceptualized and measured as stable. There are certainly empirical studies that challenge the idea of personality stability by providing evidence of developmental change over long time periods based on personality constructs and measures that expressly incorporate the notion of change (e.g., Whitbourne, Zuschlag, Elliot, & Waterman, 1992).

Fourth, some personality constructs are associated with more stability than others. Schuerger et al.'s (1989) data show that measures of psychopathology have less scale score stability than measures of "normal" personality characteristics. Perhaps "normal" personality constructs are more crystallized than psychopathological constructs and thus less error is built into the construct itself. Similarly, psychopathological constructs may be more confounded with the effects of response style variance such as social desirability and acquiescence than normal personality constructs, again compounding the noisiness of the construct.

Many researchers have tried to highlight differences in stability among the specific constructs that they chose to study. For example, Finn (1986) demonstrated that mood-related constructs (e.g., depression) had comparatively low levels of consistency, whereas Helson and Moane (1987) found that constructs related to socialization had high stability. There are shortcomings to such an approach. The identification of those dimensions on which people are changeable (i.e., states) as distinct from the more permanent individual differences dimensions needs to be tackled systematically if a comprehensive list is to be obtained (Cattell, 1963).

The interpretation of differences in stability between constructs is further complicated by age and cohort effects. Studies such as that of Helson and Moane (1987) estimate personality stability using information obtained from a single group of subjects who have been assessed at different points in time. There are limits to the generalizability of this information to other groups of people. Other studies such as that of Finn (1986) use basically a cross-sectional approach. They assess two or more groups of subjects having different ages at a single time. Here it is difficult to attribute differences in the stability of particular personality constructs to age as opposed to generational factors. More complicated designs may be needed in order to understand such age and cohort effects (Conley, 1985). At the very least, any generalizations about which personality constructs are more or less stable need to be carefully qualified.

A fifth influence on personality stability has to do with features of the persons being evaluated. Test respondents exhibit remarkable individual differences in personality stability (Assendorp, 1992; McCrae & Costa, 1990). Do some subgroups of people show more personality stability? Across studies, patient and prisoner samples show less personality test score stability than "normals" (Schuerger et al., 1989). Perhaps "non-normals" have systematically higher scale scores than "normals" and, hence, their retest scores show regression toward the mean (Windle, 1954). Alternatively, "non-normal" groups also may be more likely than normal groups to seek actively to change personality.

The other two person variables that have received attention in the literature on personality stability are age and sex differences. Some researchers report that older adults are more stable than younger adults on many traits (Finn, 1986; Schuerge et al., 1989) although others argue that stability differences after about age 30 are minimal (McCrae & Costa, 1990). Finn (1986) has asked whether older adults might just be more rigid in their self-perceptions. However, the picture of personality stability that results from self-reports does tend to be substantiated by ratings on personality information collected from others, such as spouses (McCrae & Costa, 1990). Thus, personality may indeed be more stable in older adults.

Many studies in the area of personality stability sample exclusively men or women. Yet there seems to be little evidence of an overall difference in the level of personality stability for men and women (Schuerger et al., 1989). Nonetheless, researchers interested in normative change often argue that men (Finn, 1986) and women (Helson & Moane, 1987) may be expected to change on different constructs as a function of distinct life paths or societal pressures. Few studies have been explicitly designed to compare sex differences in personality stability.

Overall, personality shows considerable stability in adulthood. The objective measures traditionally used in personality assessment may predispose us to find evidence of stability as a function of the kinds of constructs, instructions, and test construction techniques associated with these measures. Aspects of the test instrument itself, such as length or homogeneity, may moderate stability estimates, as could the length of the interval between personality assessments. Samples of "normals" and of older adults may exhibit more personality stability; sex differences in general personality stability appear to be minimal. The assumption of personality stability, at least over the short run, is central to objective personality assessment if test scores are going to predict relevant behaviors and have an impact on planning how to manage that behavior.

4.14.2 ASSESSING ADULTS IN CLINICAL SETTINGS

In this section we will provide an overview of a number of objective personality inventories that have been designed to assess adults in clinical settings. More detail on the use of the MMPI-2 will be given because it is the most widely researched and used measure. Two other measures that have recently been published to measure essentially the same clinical problem areas as the MMPI-2, BPI (Jackson, 1989) and the Personality Assessment Inventory (PAI) (Morey, 1991) will be briefly described. In the next section, several specialized measures will then be surveyed that have been developed to measure more specific clinical problems or behaviors: the MCMI to assess personality disorders; the Beck Depression Inventory (BDI; Beck, Steer, & Garbin, 1988) to assess anxiety; the State–Trait Anxiety Inventory (STAI; Spielberger, Gorsuch, & Lushene, 1970); and the Whitaker Index of Schizophrenic Thinking (WIST; Whitaker, 1973).

4.14.2.1 The Minnesota Multiphasic Personality Inventory-Revised

The MMPI-2 is the most widely used personality test with adults (Lubin, Larsen, & Matarazzo, 1984; Watkins, 1996). Keilen and Bloom (1986) found that the MMPI/MMPI-2 was the most frequently used test in custody evaluations. Developed originally in the late

1930s by Starke Hathaway and J. C. McKinley and redeveloped by Butcher, Dahlstrom, Graham, Tellegen, and Kaemmer (1989), this instrument provides a comprehensive survey of personality characteristics and clinical problems. In the original MMPI, a strictly empirical scale construction approach was followed to develop scales that would assess a patient's probable "membership" in a clinical group. An extensive amount of research has been published on the effectiveness of these measures at predicting and describing problems in adults. Research on the original version of the MMPI covered a very broad range of people—psychiatric and medical patients, substance abusers, incarcerated felons, and many other clinical groups.

In addition, a very broad range of "normals" have been studied including applicants for various jobs such as airline pilots, US Navy submariner crew members, and police and security personnel. Moreover, the instrument came to be widely employed as a personality research instrument. Butcher and Rouse (1996), in a survey of 20 years of research in clinical assessment, found that the MMPI/MMPI-2 is the most widely researched instrument with nearly twice the number of articles as the seven next leading tests. What has made the MMPI/MMPI-2 the most widely used assessment technique in the personality area? We will examine the make-up, utility, and limitations of the instrument in assessing adults.

4.14.2.1.1 Origin of the MMPI/MMPI-2

A growing dissatisfaction with subjective methods of evaluating patients in clinical situations (such as interviews and projective tests) led the original MMPI developers, Hathaway (a psychologist) and McKinley (a psychiatrist), to experiment with an objective method of clinical problem assessment. They accumulated a large number of items (symptoms, beliefs, attitudes, etc.) from tests and case material and administered them to a large group of "normal" people to serve as a comparison group. They then administered the items to well-defined and homogeneous groups of clinical patients. They empirically contrasted the responses of the patient groups with the normals to obtain items that significantly separated the groups. These items were then combined into scales for the various clinical problem areas such as depression, schizophrenia, and so forth. Once derived, the clinical scales were normed on the non-patient sample and *T* scores were developed to enable the test interpreter to determine how extreme a particular person's score was on a given scale. All of the scales were normed so that they had a mean score of 50 and a standard deviation of 10. These standard score distributions then allowed the scores to be plotted on a profile so that the interpreter would have a visual picture of how extreme a particular score was when compared with the normal. Their empirical approach produced highly valid and effective scales that predicted or described the likelihood that a person's score on a scale was in the clinical range or similar to the patient groups.

The original MMPI clinical scales have undergone very substantial study and cross-validation since their publication. They have become a standard means of objective symptom classification since their development. The clinical scales and configurations of scales, referred to as code types, have undergone substantial documentation as an objective classification schema—often referred to as "cookbooks." Researchers, for example, have cataloged the behavioral characteristics associated with their test indices allowing for automatic interpretation. That is, when a particular scale score or cluster of scales are obtained, then a well-validated set of behavioral descriptions—known as descriptors—are applied. Their objective classification approach to interpretation fostered the development of computer-based interpretation methods so popular today (Butcher, 1995; Butcher et al., 1998).

4.14.2.1.2 Measurement dimensions

(i) Validity scales

As noted earlier, it is essential to any self-reported personality assessment to appraise carefully possible invalidating conditions or circumstances. Structural elements of the test administration require evaluation to determine if extratest factors influenced the item responses. For example, were the instructions clearly presented, was the individual able to read and comprehend the items?

The MMPI-2 contains a number of scales and indexes that provide the test interpreter with information on the individual's cooperativeness and honesty in responding to the items (see Table 1 for a summary of the validity or control scales for the MMPI-2). A clear picture is obtained as to whether the person has attempted to present a false picture on the test. These scales are of several types. First, noncontent-oriented measures can provide information on whether the person was inconsistent in responding (the True Response Inconsistency or TRIN and Variable Response Inconsistency or VRIN scales). Additionally, the Cannot Say or "?' scale provides information about the person's cooperation in completing the items. Two other indexes that can provide clues to uncooperative test-taking behavior are the percentage of true and percentage of false endorsement. Records with a nearly all true or all false response pattern suggest uncooperativeness in completing the task.

Three scales have been developed to provide information about the tendency on the part of some people to claim excessive virtue or to deny problems. The L scale assesses an unsophisticated tendency to claim excessive virtue; the K scale measures test defensiveness; and the S scale (Superlative Self-presentation) assesses the tendency of some people to present themselves in a highly favorable manner (Butcher & Han, 1995).

Three scales have been developed to assess the tendency that some respondents have to claim excessive mental health symptoms. The original F scale developed by Hathaway and McKinley (1940) assesses excessive symptom checking by attending to extreme or rare responses. Those who endorse a large number of rare items are thought to be presenting an unselective or exaggerated complaint pattern. High scores on F have been associated with malingering (Berry, Baer, & Harris, 1991; Schretlen, 1988).

The F(b) scale, an infrequency scale that covers extreme items in the back of the MMPI-2 items operates much like the original F scale (Butcher et al., 1989). The newest validity measure developed by Arbisi and Ben-Porath (1995) is an extremely valuable type of infrequency scale that differs from the original F scale in an important way: the F(p) scale assesses extreme responding in a clinical sample. The F(p) scale assesses infrequent responding in a clinical setting and thereby, when extreme, suggests malingering of psychiatric symptoms.

(ii) Clinical scales

The traditional MMPI clinical scales (Hathaway & McKinley, 1940) have been updated in the MMPI-2 (Butcher et al., 1989) and have been extensively revalidated in their revised form (Archer, Griffin, & Aiduk, 1995; Butcher & Williams, 1992; Graham & Ben-Porath, 1990; Graham & Butcher, 1988). The MMPI-2 clinical scales are empirically derived measures of several well-established clinical patterns such as hypochondriasis, depression, paranoia, and schizophrenia (see Table 2).

These scales have been well studied over more than 50 years. They were kept nearly intact in MMPI-2 because of their descriptive power and ability to generalize across groups.

Two scales on the clinical profile, Mf and Si, are not empirically derived scales as were the original clinical scales but were included on the instrument to assess personality characteristics of masculine–feminine interests and social introversion.

(iii) Content scales

The expanded item pool of the MMPI-2 allowed for the development of a new set of content-based scales to assess an expanded array of problems compared with the traditional clinical measures. The 15 content scales (see Table 3) were developed according to a multimethod/multistage strategy. The 567 items were subjected to a content analysis in order to derive homogeneous content groups rationally. This approach is not as theoretically blind as it seems, since the original MMPI content had been well delineated by Wiggins (1969) and many of these constructs were still available in a modified or reduced form in the revised instruments. Moreover, the MMPI-2 committee also wrote new items to cover contents that were limited or not available in MMPI-2, for example, suicide ideation, substance abuse, and type A behavior. It therefore became possible to develop scales for a number of problem areas that have clinical relevance and are sufficiently large to assess reliably. Following provisional derivation, other scale construction strategies such as internal consistency, item scale correlation, and external validation were followed to define and improve the item groups.

Content scales provide a different type of information to the clinical interpreter's resources. These scales are viewed as direct communications between the client and the clinician. The obvious content on the scales enables the client to address problems he or she has that are considered important to address in the clinical intervention.

In addition to their value as summaries or themes considered pertinent by the patient the content scales have clearly established external validity. A number of studies have provided data on the external validity of the content scales (Ben-Porath, Butcher, & Graham, 1991; Butcher, Graham, Williams, & Ben-Porath, 1990).

4.14.2.1.3 Recent validity research for the MMPI-2

An empirically derived and based instrument requires substantial research validation in order to be useful. The MMPI-2 has been substantially researched and validated. The fact that the MMPI-2 clinical scales are the same items as in the original instrument means that all of the research on the traditional measures applies with the revised form.

Table 1 Personality characteristics associated with validity indicator elevations.

? Cannot say score

The total number of unanswered items. A defensive protocol with possible attenuation of scale scores is suggested if the ? raw score is more than 35.

L (Lie) scale

A measure of an unsophisticated or self-consciously "virtuous" test-taking attitude. Elevated scores (above 70 *T*) suggest that the individual is presenting himself or herself in an overly positive light, attempting to create an unrealistically favorable view of his or her adjustment.

F (Infrequency) scale

A high score (*T* above 90) suggests an exaggerated pattern of symptom checking that is inconsistent with accurate self-appraisal and suggests confusion, disorganization, or actual faking of mental illness. *T* scores above 100 invalidate the profile.

F(B) scale

A second infrequency scale that appears toward the back of the MMPI-2 item pool is used to assess exaggerated responding at the end of the test. This scale operates much like the original MMPI F scale in detecting malingering, random responding, or motivation to exaggerate symptoms.

F(p) scale

The Psychopathology Infrequency Scale F(p) was developed by Arbisi and Ben-Porath (1995) to assess infrequent responding in psychiatric settings. This scale is valuable in appraising the tendency for some people to exaggerate mental health symptoms in the context of patients with genuine psychological disorder.

K (Defensiveness) scale

Measures an individual's willingness to disclose personal information and discuss his or her problems. High K scores (*T* above 65) reflect an uncooperative attitude and an unwillingness or reluctance to disclose personal information. Low scores (*T* below 45) suggest openness and frankness. This scale is positively correlated with intelligence and educational level, which should be taken into account when interpreting the scores.

Variable response inconsistency

The VRIN scale consists of 49 pairs of specially selected items. The members of each VRIN item pair have either similar or opposite content; each pair is scored for the occurrence of an inconsistency in responses to the two items. The scale score is the total number of item pairs answered inconsistently. High VRIN scores are a warning that a test subject may have been answering the items in the inventory in an indiscriminate manner, and raise the possibility that the protocol may be invalid and that the profile is essentially uninterpretable.

True response inconsistency

The TRIN is made up of 20 pairs of items that are opposite in content. If a subject responds inconsistently by answering True to both items of certain pairs, one point is added to the TRIN score; if the subject responds inconsistently by answering False to certain item pairs, one point is subtracted. A very high TRIN score indicates a tendency to give True answers to the items indiscrimately ("acquiescence"), and a very low TRIN score indicates a tendency to answer False indiscriminately ("nonacquiescence"). (Negative TRIN scores are avoided by adding a constant to the raw score.) Very low or very high TRIN scores are a warning that the test subject may have been answering the inventory indiscriminately so that the profile may be invalid and uninterpretable.

S scale

A new MMPI-2 scale was developed in an effort to improve the assessment of highly virtuous responding. The subjects used in the development of the scale were 274 male airline applicants and the MMPI-2 normative sample (*N* = 1138 men and 1462 women). The S scale was initially developed by examining item response differences between airline pilot applicants, who tend to engage in superlative self-description in order to impress examiners, and normative men from the MMPI-2 restandardization sample. The scale was refined by using internal consistency methods to ensure high-scale homogeneity. A factor analysis of the resulting 50 item scale (S) yielded five factors named: Beliefs in "Human Goodness"; Serenity; Contentment with Life; Patience and Denial of Irritability and Anger; and Denial of Moral Flaws. Linear *T* score conversion tables were computed for both men and women separately and combined (unisex) using the MMPI-2 restandardization data sets. The S scale was shown to have a number of behavioral correlates reflecting the presentation of oneself as a well-controlled, problem-free person.

Table 2 Empirical correlates for MMPI-2 clinical scales.

Scale 1 (Hypochondriasis)

High-scoring people show: excessive bodily concern; somatic symptoms that tend to be vague and undefined; fatigue, pain, weakness; manifest anxiety; selfish, self-centered, and narcissistic behavior; pessimistic, defeatist, cynical outlook on life; dissatisfied and unhappy; make others miserable with whining, complaining behavior; demanding and critical of others; expresses hostility indirectly; rarely act out; dull, unenthusiastic, unambitious; ineffective in oral expression, longstanding health concerns; function at a reduced level of efficiency without major incapacity; not very responsive to therapy, tend to terminate therapy when therapist is seen as not giving enough attention and support; tend to seek medical solutions to life problems.

Scale 2 (Depression)

High-scoring people show: depressed, unhappy, and dysphoric behavior; they are pessimistic and self-deprecating; tend to feel guilty; report being sluggish; have somatic complaints such as weakness, fatigue, and loss of energy; are agitated, tense, highly-strung, and irritable; prone to worry; lack self-confidence; feel useless and unable to function; feels like a failure at school or on the job; introverted, shy, retiring, timid, and seclusive; aloof, maintain psychological distance; avoids interpersonal involvement; cautious, and conventional; has difficulty making decisions; nonaggressive; overcontrolled, deny impulses; make concessions to avoid conflict; motivated for therapy.

Scale 3 (Hysteria)

High-scoring people show: poor response to stress; they avoid responsibility through development of physical symptoms; have headaches, chest pains, weakness, and tachycardia, anxiety attacks; symptoms appear and disappear suddenly; lack insight about causes of symptoms; lack insight about own motives and feelings; lack anxiety, tension, and depression; rarely report delusions, hallucinations, or suspiciousness; psychologically immature, childish, and infantile; self-centered, narcissistic, and egocentric; expect attention and affection from others; use indirect and devious means to get attention and affection; do not express hostility and resentment openly; socially involved; friendly, talkative, and enthusiastic; superficial and immature in interpersonal relationships; show interest in others for selfish reasons; occasionally act out in sexual or aggressive manner with little apparent insight; initially enthusiastic about treatment; respond well to direct advice or suggestion; slow to gain insight into causes of own behavior; resistant to psychological interpretations.

Scale 4 (Psychopathic deviate)

High-scoring people show: antisocial behavior; rebellious toward authority figures; stormy family relationships; blame parents for problems; history of under-achievement in school; poor work history; marital problems; impulsive; strive for immediate gratification of impulses; do not plan well; act without considering consequences of actions; impatient; limited frustration tolerance; poor judgment; take risks; do not profit from experience; immature, childish, narcissistic, self-centered, and selfish; ostentatious, exhibitionistic; insensitive; interested in others in terms of *how* they can be used; likeable and usually create a good first impression; shallow, superficial relationships, unable to form warm attachments; extroverted, outgoing; talkative, active, energetic, and spontaneous; intelligent; assert self-confidence; have wide range of interests; lack definite goals; hostile, aggressive; sarcastic, cynical; resentful, rebellious; act out; antagonistic; aggressive outbursts, assaultive behavior; little guilt over negative behavior; may feign guilt and remorse when in trouble; free from disabling anxiety, depression, and psychotic symptoms; likely to have personality disorder diagnosis (antisocial or passive–aggressive); prone to worry; dissatisfied; show absence of deep emotional response; feel bored and empty; poor prognosis for change in therapy; blame others for problems; intellectualize; may agree to treatment to avoid jail or some other unpleasant experience but are likely to terminate before change is effected.

Scale 5 (Masculinity–femininity)

MALES

Scores of T over 80: Show conflicts about sexual identity; insecure in masculine role; effeminate; aesthetic and artistic interests; intelligent and capable; value cognitive pursuits; ambitious, competitive, and persevering; clever, clear-thinking, organized, logical; show good judgment and common sense; curious; creative, imaginative, and individualistic in approach to problems; sociable; sensitive to others; tolerant; capable of expressing warm feelings toward others; passive, dependent, and submissive; peace-loving; make concessions to avoid confrontations; good self-control; rarely act out. (The interpretation of high 5 scores should be tempered for males with advanced academic degrees.)

High T score between 70 and 79: May be viewed as sensitive; insightful; tolerant; effeminate; showing broad cultural interests; submissive, passive. (In clinical settings, the patient might show sex role confusion; or heterosexual adjustment problems.)

Table 2 (continued)

Low T < 35: "Macho" self-image, present self as extremely masculine; overemphasize strength and physical prowess; aggressive, thrill-seeking, adventurous, and reckless; coarse, crude, and vulgar; harbor doubts about own masculinity; have limited intellectual ability; narrow range of interests; inflexible and unoriginal approach to problems; prefer action to thought; are practical and nontheoretical; easy-going, leisurely and relaxed; cheerful, jolly, humorous; contented; willing to settle down; unaware of social stimulus value; lack insight into own motives; unsophisticated.

FEMALES
Scores of T over 70: Reject traditional female roles and activities; masculine interests in work, sports, hobbies; active, vigorous, and assertive; competitive, aggressive, and dominating; coarse, rough, and tough; outgoing, uninhibited, and self-confident; easy-going, relaxed, balanced; logical, calculated; unemotional, and unfriendly.

Low T < 35: Describe self in terms of stereotyped female role; doubts about own femininity; passive, submissive, and yielding; defer to males in decision-making; self-pity; complaining, fault finding; constricted; sensitive; modest; idealistic. (This interpretation for low 5 females does *not* apply for females with postgraduate degrees.)

Scale 6 (Paranoia)

Extremely high-scoring people (T > 80) show: frankly psychotic behavior; disturbed thinking; delusions of persecution and/or grandeur; ideas of reference; feel mistreated and picked on; angry and resentful; harbor grudges; use projection as defense; most frequently diagnosed as schizophrenia or paranoid state.

Moderate elevations (= 65–79 for males; 71–79 for females): Paranoid predisposition; sensitive; overly responsive to reactions of others; feel they are getting a raw deal from life; rationalize and blame others; suspicious and guarded; hostile, resentful, and argumentative; moralistic and rigid; overemphasizes rationality; poor prognosis for therapy; do not like to talk about emotional problems; difficulty in establishing rapport with therapist.

Extremely low (T < 35): should be interpreted with caution. In a clinical setting, low 6 scores, in the context of a defensive response set, may suggest frankly psychotic disorder; delusions, suspiciousness, ideas of reference; symptoms less obvious than for high scorers; evasive, defensive, guarded; shy, secretive, withdrawn.

Scale 7 (Psychasthenia)

High-scoring people show: anxious, tense, and agitated; high discomfort; worried and apprehensive; high strung and jumpy; difficulties in concentrating; introspective, ruminative; obsessive, and compulsive; feel insecure and inferior; lack self-confidence; self-doubting, self-critical, self-conscious, and self-derogatory; rigid and moralistic; maintain high standards for self and others; overly perfectionistic and conscientious; guilty and depressed; neat, orderly, organized, and meticulous; persistent; reliable; lack ingenuity and originality in problem solving; dull and formal; vacillates; are indecisive; distort importance of problems, overreact; shy; do not interact well socially; hard to get to know; worry about popularity and acceptance; sensitive, physical complaints; shows some insight into problems; intellectualize and rationalize resistant to interpretations in therapy; express hostility toward therapist; remain in therapy longer than most patients; makes slow but steady progress in therapy.

Scale 8 (Schizophrenia)

Very high scorers (= over 80–90) show: blatantly psychotic behavior; confused, disorganized, and disoriented; unusual thoughts or attitudes; delusions; hallucinations; poor judgment.

High (65–79): schizoid lifestyle; do not feel a part of social environment; feel isolated, alienated, and misunderstood; feel unaccepted by peers; withdrawn, seclusive, secretive, and inaccessible; avoid dealing with people and new situations; shy, aloof, and uninvolved; experience generalized anxiety; resentful, hostile, and aggressive; unable to express feelings; react to stress by withdrawing into fantasy and daydreaming; difficulty separating reality and fantasy; self-doubts; feel inferior, incompetent, and dissatisfied; sexual preoccupation, and sex role confusion; nonconforming, unusual, unconventional, and eccentric; vague, long-standing physical complaints; stubborn, moody, and opinionated; immature, and impulsive; highly-strung; imaginative; abstract, vague goals; lack basic information for problem-solving; poor prognosis for therapy; reluctant to relate in meaningful way to therapist; stay in therapy longer than most patients; may eventually come to trust therapist.

Scale 9 (Hypomania)

High-scoring people (T > 80) show: overactivity; accelerated speech; may have hallucinations or delusions of grandeur; energetic and talkative; prefer action to thought; wide range of interest; do not utilize energy wisely; do not see projects through to completion; creative, enterprising, and ingenious; little interest in routine or detail; easily bored and restless; low frustration tolerance; difficulty in inhibiting expression of impulses; episodes of irritability, hostility, and aggressive outbursts; unrealistic, unqualified optimism; grandiose aspirations; exaggerates self-worth and self-importance; unable to see own limitations; outgoing, sociable, and

Table 2 (continued)

gregarious; like to be around other people; create good first impression; friendly, pleasant, and enthusiastic; poised, self-confident; superficial relationships; manipulative, deceptive, unreliable; feelings of dissatisfaction; agitated; may have periodic episodes of depression; difficulties at school or work, resistant to interpretations in therapy; attend therapy irregularly; may terminate therapy prematurely; repeat problems in stereotyped manner; not likely to become dependent on therapists; becomes hostile and aggressive toward therapist.

Moderately elevated scores (T > 65, LE 79): Over-activity; exaggerated sense of self-worth; energetic and talkative; prefer action to thought; wide range of interest; do not utilize energy wisely; do not see projects through to completion; enterprising, and ingenious; lack interest in routine matters; become bored and restless easily; low frustration tolerance; impulsive; has episodes of irritability, hostility, and aggressive outbursts; unrealistic, overly optimistic at times; shows some grandiose aspirations; unable to see own limitations; outgoing, sociable, and gregarious; like to be around other people; create good first impression; friendly, pleasant, and enthusiastic; poised, self-confident; superficial relationships; manipulative, deceptive, unreliable; feelings of dissatisfaction; agitated; view therapy as unnecessary; resistant to interpretations in therapy; attend therapy irregularly; may terminate therapy prematurely; repeat problems in stereotyped manner; not likely to become dependent on therapists; become hostile and aggressive toward therapist.

Low scorers (T below 35): Low energy level; low activity level; lethargic, listless, apathetic, and phlegmatic; difficult to motivate; report chronic fatigue, physical exhaustion; depressed, anxious, and tense; reliable, responsible, and dependable; approach problems in conventional, practical, and reasonable way; lack self-confidence; sincere, quiet, modest, withdrawn, seclusive; unpopular; overcontrolled; unlikely to express feelings openly.

Scale 10 (Social introversion)

High-scoring people (> 65) show: socially introversion more comfortable alone or with a few close friends; reserved, shy, and retiring; uncomfortable around members of opposite sex; hard to get to know; sensitive to what others think; troubled by lack of involvement with other people; overcontrolled; not likely to display feelings openly; submissive and compliant; overly accepting of authority; serious, slow personal tempo; reliable, dependable; cautious, conventional, unoriginal in approach to problems; rigid, inflexible in attitudes and opinions; difficulty making even minor decisions; enjoys work; gain pleasure from productive personal achievement; tend to worry; are irritable and anxious; moody, experience guilt feelings; have episodes of depression or low mood.

Low (T < 45): sociable and extroverted; outgoing, gregarious, friendly and talkative; strong need to be around other people; mix well; intelligent, expressive, verbally fluent; active, energetic, vigorous; interested in status, power and recognition; seeks out competitive situations; have problem with impulse control; act without considering the consequences of actions; immature, self-indulgent; superficial, insincere relationships; manipulative, opportunistic; arouses resentment and hostility in others.

Adapted from Butcher (1989).

In addition, prior to publication of the MMPI-2 there were a number of validity studies conducted on the revised form. For example, the MMPI revision committee collected personality ratings on more than 800 couples included in the normative sample. These personality ratings clearly cross-validated a number of the original scales. Moreover, validation research was conducted on a number of samples including schizophrenics and depressives (Ben-Porath, Butcher, & Graham, 1991); marital problem families (Hjemboe & Butcher, 1991); potential child-abusing parents (Egeland, Erickson, Butcher, & Ben-Porath, 1991); alcoholics (Weed, Butcher, Ben-Porath, & McKenna, 1992); airline pilot applicants (Butcher, 1994); military personnel (Butcher, Jeffrey et al., 1990).

Since the MMPI-2 was published in 1989 a number of other validation studies have been published (Archer, Griffin, & Aiduk, 1995; Ben-Porath, McCully, & Almagor, 1993; Blake et al., 1992; Clark, 1996; Husband & Iguchi, 1995; Keller & Butcher, 1991; Khan, Welch, & Zillmer, 1993).

4.14.2.2 Basic Personality Inventory

The BPI (Jackson, 1989) was published as an alternative to the MMPI-2 for the global assessment of psychopathology. The key aims in developing the BPI were to produce a broad-band measure of psychological dysfunctioning as measured by the MMPI that was: (i) relatively short, (ii) incorporated modern principles of test construction, and (iii) showed

Table 3 Description of the MMPI-2 content scales.

1. Anxiety (ANX)

High scorers report general symptoms of anxiety including tension, somatic problems (i.e., heart pounding and shortness of breath), sleep difficulties, worries, and poor concentration. They fear losing their minds, find life a strain, and have difficulties making decisions. They appear to be readily aware of these symptoms and problems, are willing to admit to them.

2. Fears (FRS)

A high score indicates an individual with many specific fears. These specific fears can include blood; high places; money; animals such as snakes, mice, or spiders; leaving home; fire; storms and natural disasters; water; the dark; being indoors; and dirt.

3. Obsessiveness (OBS)

High scorers have tremendous difficulties making decisions and are likely to ruminate excessively about issues and problems, causing others to become impatient. Having to make changes distresses them, and they may report some compulsive behaviors such as counting or saving unimportant things. They are excessive worriers who frequently become overwhelmed by their own thoughts.

4. Depression (DEP)

High scorers on this scale show significant depression. They report feeling blue, uncertain about their future, and uninterested in their lives. They are likely to brood, be unhappy, cry easily, and feel hopeless and empty. They may report thoughts of suicide or wishes that they were dead. They may believe that they are condemned or have committed unpardonable sins. Other people may not be viewed as a source of support.

5. Health concerns (HEA)

Individuals with high scores report many physical symptoms across several body systems. Included are gastrointestinal symptoms (e.g., constipation, nausea and vomiting, stomach trouble), neurological problems (e.g., convulsions, dizzy and fainting spells, paralysis), sensory problems (e.g., poor hearing or eyesight), cardiovascular symptoms (e.g., heart or chest pains), skin problems, pain (e.g., headaches, neck pains), respiratory troubles (e.g., coughs, hay fever, or asthma). These individuals worry about their health and feel sicker than the average person.

6. Bizarre mentation (BIZ)

Psychotic thought processes characterize individuals high on the BIZ scale. They may report auditory, visual, or olfactory hallucinations and may recognize that their thoughts are strange and peculiar. Paranoid ideation (e.g., the belief that they are being plotted against or that someone is trying to poison them) may be reported as well. These individuals may feel that they have a special mission or powers.

7. Anger (ANG)

High scorers tend to have anger control problems. These individuals report being irritable, grouchy, impatient, hotheaded, annoyed, and stubborn. They sometimes feel like swearing or smashing things. They may lose self-control and report having been physically abusive towards people and objects.

8. Cynicism (CYN)

High scorers tend to show misanthropic beliefs. They expect hidden, negative motives behind the acts of others, for example, believing that most people are honest simply for fear of being caught. Other people are to be distrusted, for people use each other and are only friendly for selfish reasons. They likely hold negative attitudes about those close to them, including fellow workers, family, and friends.

9. Antisocial practices (ASP)

High scorers tend to show misanthropic attitudes like high scorers on the CYN scale. The high scorers on the ASP scale report problem behaviors during their school years and other antisocial practices like being in trouble with the law, stealing or shoplifting. They report sometimes enjoying the antics of criminals and believe that it is all right to get around the law, as long as it is not broken.

10. Type A (TPA)

High scorers report being hard-driving, fast-moving, and work-oriented individuals, who frequently become impatient, irritable, and annoyed. They do not like to wait or be interrupted. There is never enough time in a day for them to complete their tasks. They are direct and may be overbearing in their relationships with others.

11. Low self-esteem (LSE)

High scores on LSE characterize individuals with low opinions of themselves. They do not believe that they are liked by others or that they are important. They hold many negative attitudes about themselves including beliefs that they are unattractive, awkward, and clumsy, useless, and a burden to others. They certainly lack self-confidence, and find it hard to accept compliments from others. They may be overwhelmed by all the faults they see in themselves.

Table 3 (continued)

12. Social discomfort (SOD)
High scorers tend to be very uneasy around others, preferring to be by themselves. When in social situations, they are likely to sit alone, rather than joining in the group. They see themselves as shy and dislike parties and other group events.

13. Family problems (FAM)
High scorers tend to show considerable family discord. Their families are described as lacking in love, quarrelsome, and unpleasant. They even may report hating members of their families. Their childhood may be portrayed as abusive, and marriages seen as unhappy and lacking in affection.

14. Work interference (WRK)
High scorers tend to show behaviors or attitudes that are likely to contribute to poor work performance. Some of the problems relate to low self-confidence, concentration difficulties, obsessiveness, tension and pressure, and decision-making problems. Others suggest lack of family support for the career choice, personal questioning of career choice, and negative attitudes towards co-workers.

15. Negative treatment indicators (TRT)
High scorers tend to show negative attitudes towards doctors and mental health treatment. High scorers do not believe that anyone can understand or help them. They have issues or problems that they are not comfortable discussing with anyone. They may not want to change anything in their lives, nor do they feel that change is possible. They prefer giving up, rather than facing a crisis or difficulty.

Adapted from: Butcher, Graham, Williams, & Ben-Porath (1990).

empirical evidence of being able to discriminate between normal and dysfunctional persons as well as being able to predict pathological behavior.

The BPI is made up of 240 items, grouped into 12 × 20 item scales. Neurotic tendencies are measured through the scales of Hypochondriasis, Depression, Anxiety, Social Introversion, and Self-depreciation. Aspects of sociopathy are measured by Denial, Interpersonal Problems, Alienation, and Impulse Expression scales. Psychotic behavior is assessed by scales labeled Persecutory Ideas, Thinking Disorder, and to some degree, by the Deviation scale. The Deviation scale comprises 20 critical items that are intended to serve as the basis for further clinical follow up. In contrast, the definitions of the constructs reflected in the other 11 items on the BPI are based on the results of a multivariate analysis of the content underlying the MMPI and the Differential Personality Inventory (Jackson & Messick, 1971).

The strong internal psychometric properties of the BPI attest to its careful construction (Jackson, 1989). Item properties and item factor analyses support the internal structure of the instrument. Both internal consistencies and test–retest reliability estimate fall in the 0.70 to 0.80 range. Various validity studies (some published in the manual, others in the literature) show that the BPI can indeed discriminate between normal and non-normal (e.g., delinquent) persons and can, within psychiatric populations, predict a variety of clinical criteria. Norms exist for adolescents and adults, spanning a variety of sample types such as community, psychiatric, college, and forensic. However, these norms are almost entirely based on white populations. Moreover, most of the normative sample was collected using nonstandard data collection procedures. For example, booklets were mailed to subjects instead of being administered under standard conditions. In addition, each of the subjects in the normative sample responded to one-third of the items in the booklet, an artifact that makes it difficult to perform some analyses on the normative sample (e.g., alpha coefficients).

Among the difficulties that have been associated with the BPI is a lack of validity scales for identifying invalid response protocols. The one content scale that would logically appear to have some bearing on the issue of protocol validity is the Denial scale, which is described in the manual as a measure of lack of insight and lack of normal affect. Unfortunately, Denial appears to be a relatively weak scale in terms of its reliability and validity in various empirical studies (Holden et al., 1988; Jackson, 1989). Two other complaints that have been voiced are a lack of an established link to diagnostic categories and a lack of work on profile interpretation.

Overall, the BPI has shown psychometric potential as a general measure of psychopathology. The basic developmental work on it is sound. What the BPI now needs are more extensive norms along with further work on its clinical applicability.

4.14.2.3 Personality Assessment Inventory

The PAI (Morey, 1991) is another inventory of general psychopathology. The PAI is a 344 item self-report measured designed to screen for approximately the same pathological domains as the MMPI/MMPI-2. It is used to collect information related to diagnosis, and to provide input on treatment planning.

The PAI includes four validity scales, 11 clinical scales, five treatment scales and two interpersonal scales. The clinical scales are Somatic Complaints, Anxiety-related Disorders, Depression, Mania, Paranoia, Schizophrenia, Borderline Features, Antisocial Features, Alcohol Problems, and Drug Problems. Treatment scales are Aggression, Suicidal Ideation, Stress, Nonsupport, and Treatment Rejection. Interpersonal scales are Dominance and Warmth. Of these scales, 10 are further divided into subscales that are intended to measure distinct constructs. A total of 27 items are designated critical items which, according to the author, should be followed up. This does seem to be a relatively large number of scales to interpret meaningfully in view of the total number of items.

Evidence for the reliability of the 22 scales is generally good. Across normative, clinical and college samples, median alpha coefficients are all in the 0.80–0.90 range. One month test–retest coefficients are reported to be in the 0.80s in the manual and in the 0.70s in the literature (Boyle & Lennon, 1994). Interestingly, some of the lowest reliabilities are found for the validity scales, a phenomenon that has been found for the validity scales on other instruments such as the MMPI (e.g., Fekken & Holden, 1991) and may well be a function of range restriction in the scores on such scales.

Normative PAI data for the USA are extensive. Standardization samples for a census-matched group, a clinical sample representing 69 sites, and a college sample drawn from seven different US universities each number over 1000 respondents. Normative data in the manual are also reported separately by age, education, gender, and race. Normative information for other countries (Canada, Australia, the UK, etc.) would be desirable.

In view of the recency of the publication of the PAI, there are only a handful of studies that bear on its validity. The manual reports evidence of the concurrent validity of the PAI in the form of correlations with other measures of psychopathology. A number of other studies show that the PAI can discriminate between diagnostic groups. Boyle and Lennon (1994) showed that the PAI can distinguish normals, alcoholics, and schizophrenics. Schinka (1995) was further able to use the PAI to develop a typology for alcoholics that had validity with several external variables. Finally, Alterman and colleagues (1995) demonstrated that methadone maintenance patients scored differently from the normative populations.

Generally, preliminary data suggest that the PAI is a well-constructed and brief measure of psychopathology. More research on its clinical validity needs to be completed before it can be considered to be a useful measure of psychopathology in clinical settings. There are no data to support the PAI's use in lieu of the MMPI-2 which has a more substantial empirical database.

4.14.3 SPECIALIZED OR FOCUSED CLINICAL ASSESSMENT MEASURES

In this section we will address several other measures that have been developed for clinical assessment and research to assess specific or more narrowly focused characteristics rather than omnibus instruments such as the MMPI-2. Several of these instruments will be examined to illustrate their application and potential utility for evaluating specific problems in clinical settings.

4.14.3.1 Millon Clinical Multiaxial Inventory

The MCMI (Millon, 1977, 1987, 1994) was developed by Theodore Millon for making clinical diagnoses on patients. The MCMI was intended to improve upon the long-established MMPI. In contrast to the MMPI/MMPI-2, the MCMI was designed with fewer items; is based on an elaborate theory of personality and psychopathology; and explicitly focuses on diagnostic links to criteria from the *Diagnostic and statistical manual of mental disorders* (*DSM*).

The MCMI was developed rationally rather than empirically. Millon has stated in his three test manuals (1977, 1987, 1994) as well as elsewhere (Millon & Davis, 1995) that development of the MCMI is to be an ongoing process. To keep the MCMI maximally useful for clinical diagnosis and interpretation, it must be continually updated in view of theoretical refinements, empirical validation studies, and evolutions in the official *DSM* classification systems. Most updated test manuals leave the test user with the impression that the developer considered test revision a necessary evil. Very rarely do you see continuous improvement as a test developer's goal, in part because this ever-changing process makes the accumulation of a solid research base difficult.

All three MCMI versions comprise 175 true/false items. However, across versions, the exact test items have evolved through revision or replacement. The number of scales and validity indices that can be calculated from these items has also increased. The original version, the MCMI-I, had 20 clinical scales and two validity scales. The MCMI-II yielded 22 clinical scales and three validity scales. The current MCMI-III has 24 clinical scales, three modifying indices and a validity index. Many items appear on several scales making for great item overlap.

On the MCMI-III, 14 clinical scales assess personality patterns that relate to *DSM-IV* Axis II disorders. Another 10 scales measure clinical syndromes related to *DSM-IV* Axis I disorders. The modifying indices, Disclosure, Desirability, and Debasement, are correction factors applied to clinical scale scores to ameliorate respondents' tendencies to distort their responses. The validity index comprises four bizarre or highly improbable items meant to detect careless, random, or confused responding.

The relationship between scales and items is explicated in detail in the manual. Millon started with a theory-based approach to writing items, followed by an evaluation of the internal structure of the items, and finally engaged in an assessment of the diagnostic efficiency of each item for distinguishing among diagnostic groups before final placement of an item on a scale. Millon departed from usual psychometric practice in a way that results in some unfortunate complications. Item overlap across scales is permitted: on average, items appear on three different scales with differential weights. This makes scoring inordinately complex, which makes assessment of scale homogeneity complex, and in turn this makes evaluation of the empirical structure underlying the scales complex. There are technical solutions for these problems but the result is that the MCMI is not an easy instrument with which to work.

Despite its psychometric drawbacks, the theory underlying the MCMI is generally agreed to be elegant and a substantial asset (McCabe, 1987; Reynolds, 1992). Each dimension measured by the test has a clear conceptual link to Millon's theory of psychopathology. Such a theory allows for the generation of clinical inferences based on a small number of fundamental principles (Millon & Davis, 1995). Not only do these inferences guide measurement, but also they enhance understanding of the constructs, bear on practical treatment decision, and produce research hypotheses.

One of the stated goals of the MCMI is to place patients into target diagnostic groups. To this end, the MCMI scales are directly coordinated with the *DSM* diagnostic categories. How well does the MCMI live up to its aim? The manuals report good evidence of diagnostic efficiency. However, the recent literature (available on the MCMI-I and MCMI-II) suggests the following three generalizations. First, the MCMI has only modest accuracy for assigning patients to diagnostic groups across a variety of clinical criteria (e.g., Chick, Martin, Nevels, & Cotton, 1994; Chick, Sheaffer, Goggin, & Sison, 1993; Flynn, 1995; Hills, 1995; Inch & Crossley, 1993; Patrick, 1993; Soldz, Budman, Demby, & Merry, 1993). Second, the MCMI may be better at predicting the absence than the presence of a disorder (Chick et al., 1993; Hills, 1995; Soldz et al., 1993). Third, the MCMI may be better at predicting some types of disorders than others but there is little agreement on which ones (Inch & Crossley, 1993; Soldz et al., 1993).

One source of the difficulty may be the base rate scores. Raw scores on scales are weighted and converted to base rate scores. The base rate scores reflect the prevalence of a particular personality disorder or pathological characteristic in the overall population. Their use is intended to maximize the number of correct classifications relative to the number of incorrect classifications when using the MCMI to make diagnoses (Millon & Davis, 1995). If the estimated base rates for the various diagnostic categories are poor, then the predictive accuracy of the MCMI can be expected to be poor (Reynolds, 1992).

One negative consequence of the type of norms used in the development of the MCMI inventories is that they do not discriminate between patients and normals. Use of the MCMI assumes that the subject is a psychiatric patient. Consequently, the MCMI overpathologizes individuals who are not actually patients. The MCMI should not be used where issues of normality need to be addressed. For example, if the test were used in family custody evaluations or personnel screening, the test interpretation would appear very pathological—it cannot do otherwise.

How does the MCMI compare to the MMPI? The MCMI publisher appears to emphasize that the MCMI and MMPI-2 measure different characteristics and the MCMI is shorter to administer to patients. Whereas the MMPI measures a broad range of psychopathology, the MCMI has its premier focus on the assessment of personality disorders. Consonant with its rational construction, the elaborate theoretical underpinnings of the MCMI are impressive. In contrast, however, the test literature that supports the validity of the MMPI/MMPI-2 is not available for the MCMI. Validation research on it has not proceeded at a very high pace. Whether the MCMI will have either the clinical utility or the heuristic value that the MMPI enjoys remains unanswered until more clinical research, and perhaps more refinements, are undertaken with the MCMI.

4.14.3.2 The Beck Depression Inventory

The BDI was first introduced in 1961, and it has been revised several times since (Beck et al., 1988). The BDI has been widely used as an assessment instrument in gauging the intensity of depression in patients who meet clinical diagnostic criteria for depressive syndromes. However, the BDI has also found a place in research with normal populations, where the focus of use has been on detecting depression or depressive ideation.

The BDI was developed in a manner similar to the MMPI: clinical observations of symptoms and attitudes among depressed patients were contrasted to those among nondepressed patients in order to obtain differentiation of the depressed group from the rest of the psychiatric patients. The 21 symptoms and attitudes contained in the BDI reflect the intensity of the depression; items receive a rating of zero to three to reflect their intensity and are summed linearly to create a score which ranges from 0 to 63. The 21 items included reflect a variety of symptoms and attitudes commonly found among clinically depressed individuals (e.g., Mood, Self-dislike, Social Withdrawal, Sleep Disturbance). The BDI administration is straightforward, and it can be given as an interview by the clinician or as a self-report instrument (requiring a fifth or sixth grade reading level).

The BDI is interpreted through the use of cut-off scores. Cut-off scores may be derived based on the use of the instrument (i.e., if a clinician wishes to identify very severe depression, then the cut-off score would be set high). According to Beck et al. (1988), the Center for Cognitive Therapy has set the following guidelines for BDI cut-off scores to be used with affective disorder patients: scores from 0 through 9 indicate no or minimal depression; scores from 10 through 18 indicate mild to moderate depression; scores from 19 through 29 indicate moderate to severe depression; and scores from 30 through 63 indicate severe depression.

Two important issues must be considered by clinicians regarding the results of the BDI. Unlike the MMPI/MMPI-2 and other major self-report instruments, the BDI has no safeguards against faking, lying, or variable response sets. Thus, clinicians are warned against this drawback of the BDI in assessing depressive thoughts and symptoms. In settings where faking or defensiveness are probable threats to the validity of the test, clinicians may need to reconsider their use of the BDI. The other issue pertains to the state–trait debate in assessment. The BDI is extremely sensitive to differences in the instructions given to an examinee such that certain instructions yield a state-like index of depressive thinking, whereas, other instructions yield a more trait-like index of depressive thinking. Again, clinicians are encouraged to use caution when administering the BDI and to tailor the administration instructions to the type of index (state or trait) that is desired.

In their review of the psychometric properties of the BDI, Beck et al. (1988) reported high internal consistency reliability of the instrument among both psychiatric and nonpsychiatric populations. The authors also reported that the BDI closely parallels the changes in both patient self-report and clinicians' ratings of depression (i.e., the BDI score accurately reflects changes in depressive thinking). Finally, they also presented evidence for the content, concurrent, discriminant, construct, and factorial validity of the BDI.

The acceptable reliability and validity of the BDI have helped make it a widely used objective index of depressive thinking among clinicians. Perhaps the most obvious use of the BDI is as an index of change in the level or intensity of depression. With an increasing focus on managed healthcare and accountability by psychotherapeutic service providers, the BDI offers a reliable and valid index of depressive symptoms and attitudes which can be used effectively to document changes brought about in therapy.

4.14.3.3 The State-Trait Anxiety Inventory

The STAI was developed by Spielberger et al. (1970) to measure anxiety from the perspective of states vs. traits. The state measurement assesses how the individual feels "right now" or at this moment. Subjects are asked to rate the intensity of their anxious feelings on a four point scale as to their experience of feelings in terms of: not at all, somewhat, moderately so, or very much so. The trait anxiety measure addresses how the individuals generally feel by rating themselves on a four-point scale: almost never, sometimes, often, or almost always.

Since it was developed in 1966 the STAI has been translated into over 48 different languages and has been widely researched in a variety of clinical and school settings (Spielberger, Ritterband, Sydeman, Reheiser, & Unger, 1995). The evidence for construct validity of the STAI comes from a variety of sources, for example, correlations with other anxiety measures (Spielberger, 1977), clinical settings (Spielberger, 1983), and medical and surgical patients (Spielberger, 1976). Nonetheless, there has been general debate in the literature about the conceptual and practical benefits of the trait vs. state distinction.

The STAI has become a very widely used measure in personality and psychopathology research in the USA and in other countries. However, the state-trait inventories have not been as broadly used as clinical assessment instruments.

4.14.3.4 Whitaker Index of Schizophrenic Thinking

The WIST (Whitaker, 1973, 1980) was developed to measure the type of thought impairment that differentiates between schizophrenic and "normal" thought processes. The WIST is intended to be individually administered as a screening tool or as one part of a battery of tests. Its multiple choice format makes the WIST a test that is easy to give and to score.

On the WIST, schizophrenic thought is defined as a discrepancy between actual and potential performance on cognitive reasoning tasks. This impaired thinking has three components: (i) a degree of illogicality, as reflected in inappropriate associations and false premises; (ii) a degree of impairment relative to previous performance, as reflected in slowness; and (iii) a degree of unwittingness, as reflected in unawareness of the incorrectness of responses. Whitaker's definition of schizophrenic thought is carefully explicated in the manual, making it possible for the test user to understand exactly what the WIST is measuring. Whitaker, however, has been criticized for basing his definition on a narrow reading of the literature on schizophrenic thought disorder (Payne, 1978).

The WIST itself is made up of 25 multiple choice items that are divided into three subtests: Similarities, Word Pairs, and New Inventions. Each item consists of a stimulus and five response options that differ in degree of illogicality. To illustrate, consider this sample item for the Similarities subtest: car: automobile, tires, my transportation, jar, smickle. The correct answer receives a score of 0; a loose association, reference idea, clang association, and nonsense association would receive scores of 1, 2, 3, and 4, respectively. The test administrator presents for a second time any items that the respondent answered incorrectly on the initial test taking.

Three scores are calculated for the WIST: total Score for all response alternatives selected either in the original or in the second enquiry phase; total Time for the initial completion of the WIST; and an overall Index that combines WIST Score and WIST Time. Presumably the WIST Score and Time components are added together because they both relate to schizophrenic thought disorder. However, a review of the empirical data supporting this conceptualization finds mixed results at best (Fekken, 1985). One view is that the predictive efficiency of the WIST is not enhanced by including the Time component.

There are two parallel forms of the WIST which differ in content. Items on Form A are intended to be stressful or anxiety provoking. They assess oral-dependency, hostility, and manifestly sexual content. The content of Form B is neutral. There has been little formal evaluation of the comparability of the two forms. Although some studies have reported similar rates of diagnostic efficiency for the two forms (Evans & Dinning, 1980; Leslie, Landmark, & Whitaker, 1984), overall validity evidence would suggest that Form A is stronger than Form B. Additional work to clarify the comparability of Forms A and B would have implications for selecting which form to use and for using these alternate WIST forms to assess changes in symptomatology.

There is relatively little information on reliability available on the WIST. The manual does report intratest reliabilities of the two WIST forms as Hoyt's reliability coefficients of around 0.80. Test–retest reliability data, either on the WIST subscores or subscales, are not provided in the manual nor do they appear to be readily available in the literature. Similarly, alternate forms of reliability, calculated as correlations between subscales, or subscores, are not readily available.

There is reasonable evidence for the convergent validity of the WIST. Two reviews report that WIST scores tend to have a 60–70% agreement with systems for diagnosing schizophrenia (Fekken, 1985; Grigoriadis, 1993). The WIST has been empirically associated with other indices of schizophrenia such as the MMPI/MMPI-2 Sc scale (Evans & Dinning, 1980; Fishkin, Lovallo, & Pishkin, 1977; Grigoriadis, 1993) although not with other schizophrenia indices including conceptually relevant SCL-90 scales (Dinning & Evans, 1977) and the New Haven Schizophrenic Index (Knight, Epstein, & Zielony, 1980).

Discriminant validity of the WIST has been harder to establish. The WIST has difficulty distinguishing among different psychiatric diagnostic groups (e.g., Burch, 1995; Pishkin, Lovallo, & Bourne, 1986). This is a serious shortcoming because the WIST is likely to be used in clinical settings precisely to help make such distinctions. A second problem with discriminant validity has been the tendency of the WIST to correlate negatively with measures of general cognitive ability. Based on such data one could share the view of at least one pessimistic reviewer and claim that the WIST has no demonstrated use (Payne, 1978).

Alternatively, the WIST may have a role in a comprehensive assessment battery. The WIST has never been promoted as a stand-alone test, nor has it ever been promoted as a comprehensive measure of the full range of schizophrenic symptomatology. Rather, the data on the WIST may be thought of as a general measure of cognitive deficit rather than cognitive deficit specific to schizophrenia. Thus, it may provide one objective source of data for accepting or rejecting a more general diagnosis of psychosis.

4.14.4 NORMAL RANGE PERSONALITY ASSESSMENT

Identification and description of psychological disorder is but one reason to administer a personality measure to an adult. Objective personality measures also are widely used outside the clinic or hospital setting for normal range assessment situations. Several objective personality measures will be discussed regarding their use in research, educational, vocational assessment, and personnel selection.

4.14.4.1 Objective Personality Measures in Research

4.14.4.1.1 The Five Factor Model (the Big Five)

One of the most popular current conceptualizations being studied today involves taxonomies of personality traits based on factor analytic methods and is commonly referred to as the "Big Five," or the Five Factor Model (FFM). As Butcher and Rouse (1996) note in their review, some personality researchers have rejected the FFM as an end-all to personality trait theory, while others in the area of personality research continue to embrace it. Among the proponents of the FFM are Costa and his colleagues, who have proposed the NEO Personality Inventory (NEO-PI) as a self-report measure of the FFM personality dimensions (Costa & McCrae, 1992). The FFM consists of five factor-analytically derived dimensions of personality. The five dimensions (are Neuroticism (N), Extroversion (E), Openness to Experience (O), Agreeableness (A), and Conscientiousness (C). Neuroticism has long been a familiar adjective among clinicians for describing people who tend to experience psychological distress. At the opposite end of the Neuroticism dimension is Emotional Stability, which represents the tendency to stay on a psychologically even keel. Extroversion encompasses the concepts of positive emotionality, sociability, and activity. The Extroversion dimension is rather broad in its scope, although lay people often use the term narrowly to refer to general "outgoingness." Openness to Experience represents, broadly, a person's level of constriction in their experiencing of the world; it is often associated with creativity (and even hypnotizability). Agreeableness represents the dimension of interpersonal behavior; the counterpart of Agreeableness is Antagonism. Finally, Conscientiousness represents a dimension of scrupulous organization of behavior.

4.14.4.1.2 NEO Personality Inventory

The NEO-PI is a 181-item inventory designed to index the FFM personality dimensions (N, E, O, A, and C); the NEO-PI also yields several subscales of the N, E, and O dimensions (Costa & McCrae, 1992). There is a self-report form of the NEO-PI as well as an observer-rating form. Although the authors of the NEO-PI argue for its utility in clinical settings, the instrument has been studied almost exclusively in nonclinical populations. One example of a recent investigation using the NEO-PI in research with psychiatric samples is the examination of differences in stimulus intensity modulation among older depressed individuals with and without mania features (Allard & Mishara, 1995). The NEO-PI was used to examine the hypothesis that stimulus intensity augmenters with unipolar depression would be introverted, whereas reducers with bipolar depression would be extroverted. Determinations of depression with and without mania features were based on scores on the MMPI. Costa and McCrae (1992) point to the NEO-PI as a useful assessment tool in aiding the clinician with understanding the client, selection of treatment, and even anticipating the course of therapy. However, the NEO-PI has not found wide use among clinicians to date (Butcher & Rouse, 1996).

Unfortunately, the NEO-PI is very susceptible to faking (Bailley & Ross, 1996) and does not contain validity indices to detect deviant response sets.

4.14.4.1.3 Multidimensional Personality Questionnaire

The Multidimensional Personality Questionnaire (MPQ) is a 300-item self-report instrument that was developed by Tellegen (unpublished manuscript) in an attempt to clarify the "self-view domain" in personality research. Tellegen used a classical iterative test construction approach involving several rounds of factor analysis to come up with the 11 primary scales, six validity scales, and three "higher-order" factors. The 11 primary scales (which include the dimensions of Social Potency, Control, Harm Avoidance, Well-being, Aggression, and others) load onto the three higher-order scales, which represent the familiar personality domains of Positive Affectivity, Negative Affectivity, and Constraint. The six validity indices include VRIN and TRIN, which are conceptually similar to those on the MMPI-2.

The MPQ is not as widely used as other objective personality measures in either the clinical or the research domain. However, recent investigations suggest a place for the MPQ in normal range and clinical personality assessment. For example, Kuhne, Orr, and Baraga (1993) demonstrated the utility of certain MPQ scales for discriminating among veterans with and without post-traumatic stress disorder. Krueger et al. (1994) administered the MPQ to adolescents in their community-based longitudinal study and found that certain MPQ scales were useful in distinguishing those who engaged in delinquency from those who abstained. These two reports suggest the utility of the MPQ both in clinical settings and in normal range personality assessment.

4.14.4.1.4 Personality Research Form

One well-known measure of normal personality is the Personality Research Form (PRF). Developed by Douglas N. Jackson (1984), the PRF is a true/false, multiscale measure of 20 of the psychosocial needs (e.g., achievement, aggression, sociability) originally defined by Henry Murray (1938). Many psychometrics texts hold up the PRF as a model of the construct approach to test construction. Indeed, much of the appeal of the PRF lies in its ability to measure a large number of normal personality characteristics while minimizing both scale intercorrelations and the influence of social desirability and acquiescence. Moreover, a variety of validity studies have been published in the 1980s and 1990s supporting the psychometric soundness of the PRF. Critics of the PRF complain that despite its technical elegance the PRF does not reflect an integrated model of personality, which limits its applicability to real-life testing situations. Recent research, however, shows that the content assessed by the PRF may be well described by the Five Factor structure (Paunomen, Jackson, Trzebinski, & Fosterling, 1992). In research the popularity of the PRF remains high as attested to by the number of references in bibliographies, such as the one produced by MacLennan in 1991, which lists over 375 studies featuring the PRF in the literature.

4.14.4.1.5 Sixteen Personality Factor Test

The 16PF was originally developed in the 1940s by Raymond Cattell to measure the primary factors of normal personality. At that time, Cattell's unique contribution was to apply factor analysis as a method for uncovering the full scope of personality. The fifth and current edition of the 16PF (Cattell, Cattell, & Cattell, 1993) measures the well-known 16 personality factors, plus it summarizes these factors into five global factors which again bear similarity to the well-known "Big Five." The global factors are: extroversion, anxiety, tough-mindedness, independence, and self-control. Relative to earlier editions, the fifth editions includes updated language; fewer items; and improved reliability and response style scales to measure impression management, infrequent responding, and acquiescence. Because of the recency of the publication of the fifth edition, there are few studies pertaining to its validity. However, a large database supports the validity of earlier editions of the 16PF. The 16PF has applicability in clinical, educational, organizational, and research settings. With the expansion of its interpretive reports and profiles, the 16PF would appear to be particularly useful in personal or vocational counseling settings.

4.14.4.1.6 California Psychological Inventory

The CPI developed by Gough (1957) is a multiscale, objective, self-report instrument used with normal range and psychiatric populations (Megargee, 1972). The CPI is similar in structure and content to the MMPI (and the MMPI-2). In fact, many of the items on the CPI are identical in wording to the items on the MMPI. The CPI focuses on "everyday" concepts about personality, such as dominance and responsibility among others. Eighteen scales (divided into four classes) are derived from the CPI; the results of the test are interpreted by reference to the plotted profile of standard scores. The body of literature using the CPI in normal range assessment is quite extensive in both quantity and breadth. Investigations include the use of the CPI to identify personality types, based on profiles, among a group of college students (Burger and Cross, 1979) and an examination of the underlying personality structure as measured by the CPI, again using a sample of college students (Deniston and Ramanaiah, 1993). The CPI also has been employed in the assessment of psychiatric samples. Especially noteworthy is the utility of the CPI with criminal samples (see Laufer, Skoog, and Day, 1982, for a relevant review of this literature).

Some specific applications of psychological tests in "normal range" settings are now described.

4.14.4.2 Objective Personality Measures in Educational/Vocational Assessment

The use of objective personality measures has become increasingly popular among professionals in the field of educational/vocational assessment. Research has identified the FFM, the NEO-PI, and the CPI as particularly useful in educational/vocational assessment.

4.14.4.2.1 FFM

The Big Five personality dimensions of the FFM have been studied in several contexts related to educational/vocational assessment. Moreover, because the FFM is a theoretical concept, various instruments have been used to assess the relationship between the Big Five personality dimensions and various educational/vocational assessment variables. Two recent investigations illustrate the utility of the Big Five personality dimensions in identifying candidates for admission to educational institutions and identifying characteristics among students in various university programs. Williams, Munick, Saiz, and Formy-Duval (1995) found that a mock graduate school admissions board (composed of graduate school faculty) favored for admission those hypothetical candidates whose applications reflected high ratings on the Big Five dimensions of Conscientiousness and Openness to Experience. Conversely, the Big Five dimensions of Extroversion and Agreeableness were not associated with a favorable impression of hypothetical candidates. Kline and Lapham (1992) assessed the Big Five personality dimensions among a group of college students to examine personality differences among the various fields of study (i.e., between different college majors). Students of various majors were not discriminated by levels of either Neuroticism or Extroversion. However, students in two fields of study (science and engineering) were marked by high ratings on the Big Five personality dimensions of Conscientiousness and Conventionality.

4.14.4.2.2 NEO-PI

The personality dimensions that underlie the NEO-PI appear to be related to at least one well-known typology of vocational personalities (which, in turn, correspond to vocational preferences). Gottfredson, Jones, and Holland (1993) found a relationship between the Big Five personality dimensions assessed by the NEO-PI and the six vocational personality dimensions proposed by Holland (assessed with the Vocational Preferences Inventory). In general, there was overlap among two to four of the significant factors extracted from each of the assessment instruments. However, the NEO-PI Neuroticism, Likability, and Control factors were not represented in the Holland vocational personality dimensions, which suggests a distinctive and qualitatively different role for objective personality assessment in vocational counseling. Other work with the NEO-PI has shown that two of the Big Five personality dimensions, Neuroticism and Agreeableness, are strongly related to occupational burnout among healthcare workers (Piedmont, 1993). Healthcare workers with higher ratings on the Neuroticism dimension were more likely to experience occupational burnout. Conversely, workers with higher ratings on the Agreeableness dimension were less likely to succumb to occupational burnout.

4.14.4.2.3 CPI

The CPI is one of the most widely used personality instruments in normal range assessment in educational/vocational settings. Walsh (1974) examined personality traits among college students identified as making hypothetical career choices that were either congruent or incongruent with their vocational personality type (as proposed by Holland). It was found that congruent students could be described by their CPI profiles as socially accepted, confident, and planful, whereas incongruent students could be described as impulsive, unambitious, and insecure. The well-known Strong Vocational Interest Blank (SVIB) used commonly among vocational and educational counselors is related to various personality traits as well. Johnson, Flammer and Nelson (1975) found a relationship among SVIB factors and CPI personality factors, especially those related to the global introversion/extroversion personality dimension.

4.14.4.2.4 MMPI/MMPI-2

Although it was not designed for educational research or placement purposes the MMPI/MMPI-2 has been among the most frequently employed instruments in this context. In a recent survey of test use in personnel and educational screening the MMPI has been employed effectively in a number of studies, for example: Anderson (1949), Appleby and Haner (1956), Applezweig (1953), Barger and Hall (1964), Barthol and Kirk (1956), Burgess

(1956), Centi (1962), Clark (1953, 1964), and Frick (1955) to mention only a few.

It appears evident that personality assessment contributes information independent of direct educational/vocational interest measures. There is extensive information available on the use of the MMPI/MMPI-2 in this setting. As demonstrated in the research with the NEO-PI and the CPI, objective personality assessment instruments yield information relevant to vocational assessment over and above that given by narrowly defined vocational personality assessments (like the one proposed by Holland). Moreover, elements of the FFM and independent personality constructs of the CPI have proven their utility in educational assessment in diverse areas such as admissions to educational institutions and choice of major fields of study. Clearly, objective personality assessment has carved out a valuable niche in normal range educational/vocational assessment.

4.14.4.3 Personnel Screening

Among the earliest and most extensive uses of personality tests with normals has been for the purpose of employment screening. The first formal North American, English language personality inventory, the Woodworth Personnel Data Sheet, was developed to screen out unfit draftees during World War I. A number of other personality questionnaires were developed in the 1930s to aid in personnel selection decisions.

The development and use of the MMPI during World War II provided a means for assessment psychologists to detect psychological problems that might make people unsuitable for key military assignments. Early research on the use of the MMPI centered around pilot selection and selection of nuclear submarine crewman. Following World War II, the MMPI came to be widely used in personnel selection particularly for occupations that required great responsibility or involved high stress such as air flight crews (Butcher, 1994; Cerf, 1947; Fulkerson, Freud, & Raynor, 1958; Fulkerson & Sells, 1958; Garetz & Tierney, 1962; Geist & Boyd, 1980; Goorney, 1970; Jennings, 1948); police and other law enforcement personnel (Beutler, Nussbaum, & Meredith, 1988; Beutler, Storm, Kirkish, Scogin, & Gaines, 1985; Butcher, 1991; Dyer, Sajwaj, & Ford, 1993; Hargrave & Hiatt, 1987; Saxe & Reiser, 1976; Scogin, & Beutler, 1986; Scogin & Reiser, 1976); and nuclear power employees (Lavin, Chardos, Ford & McGee, 1987).

Following the revision of the MMPI and publication of the MMPI-2, the revised instrument has been used in personnel screening (Butcher & Rouse, 1996) and currently is the most frequently used personality measure in personnel screening situations, particularly when the position is one that requires good mental health, emotional stability, and responsible behavior.

The MMPI-2 is usually employed in personnel selection to screen out candidates who are likely to have psychological problems from critical occupations such as police officer, airline pilot, and nuclear power control rooms, fire department, or air traffic control personnel.

4.14.4.4 Other Personality Measures in Personnel Selection

Objective measures of personality characteristics have a role in personnel selection similar to that in educational/vocational assessment. Namely, professionals in the field of personnel selection are interested in knowing which personality variables aid in the selection of quality employees. The literature suggests a valuable role for objective personality measures in the normal range assessment field of personnel selection.

4.14.4.5 The 16PF

One of the most widely used personality scales for employment screening is the 16PF. This inventory, with broad-ranging employment-relevant personality items, has been widely used in different contexts including: law enforcement (Burbeck & Furnham, 1985; Fabricatore, Azen, Schoentgen, & Snibbe, 1978; Hartman, 1987; Lawrence, 1984; Lorr & Strack, 1994; Topp & Kardash, 1986); pilots (Cooper & Green, 1976; Lardent, 1991); cabin crew personnel (Furnham, 1991); managers (Bartram, 1992; Bush, & Lucas, 1988; Chakrabarti, & Kundu, 1984; Henney, 1975); occupational therapists (Bailey, 1988); church counselors (Cerling, 1983) and teachers (Ferris, Bergin, & Wayne, 1988). The 16PF provides information about personality functioning and is typically employed to screen employees for positive personality features.

4.14.4.6 FFM

Barrick and Mount (1991) conducted a meta-analysis of the Big Five personality dimensions and their relationship to three criterion variables (job proficiency, training proficiency, and personnel data) within five occupational groups (professionals, police, managers, skilled/semiskilled and sales). Conscientiousness was related to each of the five occupational groups. Additionally, Conscientiousness was related to the three criterion variables. These findings lead the authors to conclude that Conscientiousness is a personality trait related to job performance across occupational types. In a similar vein, Dunn, Mount, Barrick, and Ones (1995) found that the Conscientiousness personality dimension was related to managers' ratings of applicant hireability. This held true for various job types (medical technologist, carpenter, secretary, etc.). Taken together, these two reports suggest that professionals in the field of personnel selection can gain valuable information from objective personality measures of the FFM. Specifically, the Conscientiousness dimension, when taken with other relevant application information, may be a valuable discriminator among prospective job applicants.

4.14.4.7 NEO-PI

While research suggests that the Big Five personality dimensions add qualitative information to the personnel selection process, it may be that the various instruments used to measure the Big Five have differential validity across populations. Schmit and Ryan (1993) administered a shortened version of the NEO-PI to a sample of college students and to a sample of government job applicants. The FFM structure fitted the student population better than it fitted the job applicant population, which suggests a note of caution in putting too much weight on the Big Five personality dimensions in personnel selection. The authors note that job applicants are under different situational demands, which may affect their approach to a personality questionnaire (e.g., they may adopt a defensive response style). The lack of validity scales to assess response styles clearly limits the NEO-PI for this application. A recent study by Bailley and Ross (1996) showed that the NEO-PI is quite vulnerable to faking and is limited in not having scales to detect deviant response attitudes.

4.14.4.7.1 CPI

The NEO-PI and other personality measures have been examined in personnel selection studies covering a wide range of occupational groups (managers, secretaries, carpenters, etc.). However, the CPI has a long tradition of use in the selection of a specific occupation: law enforcement officers. Hargrave and Hiatt (1989) examined the ability of the CPI scales to differentiate police cadets rated by their instructors as suitable or unsuitable for the job of law enforcement officer. Several scales (including Sense of Well-being, Sociability, and Social Presence) differentiated suitable from unsuitable cadets. In the second study of the report, the authors compared incumbent law enforcement officers who either had or had not experienced serious on-the-job problems (e.g., providing drugs to inmates, excessive use of force). The Socialization scale was among the best discriminators between groups. The authors concluded that the CPI is a useful aid to the selection of law enforcement officers.

In addition to the literature on law enforcement screening, the CPI may be useful as an index of work performance in other fields. Toward this end, Hoffman and Davis (1995) validated the Work Orientation and Managerial Potential scales for the CPI on groups of employees in an entertainment facility. However, several of the original CPI scales performed as well as the two new scales in predicting job performance, which questions the need for additional CPI scales in the selection of personnel.

In summary, the use of objective personality measures in the selection of job applicants has proven a worthwhile endeavor overall. The Big Five personality dimensions, especially Conscientiousness, might be useful to the personnel selection process especially in the assessment of conscientiousness. Professionals involved in the screening of law enforcement candidates can use the CPI to differentiate suitable from unsuitable candidates. The CPI may also be useful in discriminating among groups of job applicants (although its primary use has been in the law enforcement field).

The scales on the 16PF have been shown to be relevant to personality descriptions that are useful in personnel selection. Finally, when it comes to evaluating potential psychopathology in potential employees the MMPI-2 is usually the instrument most employed.

Although objective personality measures appear to have a place in personnel selection, all information on the candidate must be weighed, as several personality researchers have noted the problem of response sets associated with the situational demands of the application process. Specifically, job applicants may feel under pressure to make a good impression on their prospective employer and they may subsequently present themselves as overly virtuous or defensive.

4.14.5 SUMMARY

Human fascination with the concept of personality lead to the nineteenth century invention of the first objective personality test.

As with those very early personality measures, many of today's objective personality inventories are self-reports. The clinician's first concern when utilizing an objective personality measure is whether or not a client can accurately reveal information about his or her personality through a self-report instrument. Many objective personality instruments incorporate indices of test-taking attitudes (e.g., the Lie scale of the MMPI/MMPI-2) which allow the clinician to gauge a client's level of insight and willingness to self-disclose. Additionally, research shows that clients who do cooperate with testing produce personality profiles that match external criteria (e.g., clinician's notes and observations regarding the patient). Essentially, most clients are able to reveal their personalities competently through self-report measures.

Once a client is able to self-disclose information regarding his or her personality, the scale scores that are produced appear to be quite stable over time. Thus, most of the objective personality measures manage to capture trait (as opposed to state) characteristics. Five factors exhibit influence on the stability of personality: (i) instrument characteristics, (ii) length of retest interval, (iii) operationalization of personality as a stable construct for test construction, (iv) the extent to which a particular personality construct is associated with stability, and (v) person variables of the test-taker.

Several objective personality measures are designed to assess adults in clinical settings. The most well-known and widely used objective personality inventory in clinical settings is the MMPI-2, which provides a comprehensive survey of personality characteristics and clinical problems. The Basic Personality Inventory (BPI) and the Personality Assessment Inventory (PAI) are alternatives to the MMPI-2, but neither is as widely used as the MMPI-2. Several other objective measures have been developed for specialized or focused clinical use including the Millon Clinical Multiaxial Inventory (MCMI) designed for making personality diagnoses; the Beck Depression Inventory (BDI), which assesses depressive ideation; the State-Trait Anxiety Inventory (STAI) designed to assess both long-term and short-term anxiety features; and the Whitaker Index of Schizophrenic Thinking (WIST) designed to measure the type of thought impairment that differentiates between schizophrenic and "normal" thought processes.

While certain objective personality measures were developed for and have been used widely in clinical setting, several inventories have gained use in research and other normal range assessment settings. Many researchers utilize inventories that measure the Big Five (or Five Factor Model, FFM) personality traits: Neuroticism (N), Extroversion (E), Openness to Experience (O), Agreeableness (A), and Conscientiousness (C). The NEO Personality Inventory (NEO-PI) assesses N, E, and O and has been used as an index of the Big Five in research. The Multidimensional Personality Questionnaire (MPQ) assesses the broad personality domains of Positive Affectivity, Negative Affectivity, and Constraint. The MPQ contains two validity indexes (VRIN and TRIN) common to the MMPI-2, which make the MPQ appealing to many researchers. Other objective personality instruments that have been used widely in research include the Personality Research Form (PRF), a measure of several psychosocial needs; the 16PF, which measures global factors similar to the Big Five; and the California Psychological Inventory (CPI), designed to assess "everyday" concepts about personality.

Finally, professionals working in the fields of educational/vocational assessment and personnel selection have found use for several objective personality measures. The 16PF, the CPI, and, most commonly, the MMPI/MMPI-2 have been used in both of these settings. Objective personality instruments give professionals information about an individual's personality which would not be obtained through standard applications or interviews. Thus, professionals can use objective personality inventories as an efficient method of obtaining more information to aid them in their task of advising clients about educational/vocational decisions or advising employers in the selection of personnel.

Whether one needs a tool to assess adult personality in clinical, research, or industry settings, there is probably an objective personality inventory to fit the bill. Many of today's objective inventories offer the efficiency of providing a comprehensive assessment of personality functioning, and some even provide computerized interpretation of the personality profile. Perhaps most importantly, most of the objective personality inventories available commercially are standardized instruments that can assess adult personality validly and reliably, which means these instruments can be used over the course of a client's treatment to document goals for change—a feature that is becoming increasingly important to clinicians in this era of managed healthcare.

4.15.1 INTRODUCTION

Projection, as first formulated by Freud (1962) and later elaborated in his presentation of the Schreber case (Freud, 1958), consists of attributing one's own characteristics to external objects or events without adequate justification or conscious awareness of doing so. Frank (1939) suggested that personality tests in which there is relatively little structure induce a subject to "project upon that plastic field . . . his private world of personal meanings and feelings" (pp. 395, 402). By linking the concept of projection to the response process in such measures as the Rorschach Inkblot Method and the Thematic Apperception Test (TAT), Frank gave birth to the so-called projective hypothesis in personality assessment. His observations about what he called "projection measures" led to the Rorschach, the TAT, and other assessment methods involving some ambiguity being routinely designated as projective tests.

This chapter begins with some observations concerning the nature of objectivity and subjectivity in personality assessment methods and the role of structure and ambiguity in different types of projective techniques. It then turns to the value and utility of projective assessment and the applicability of projective methods in clinical work with young people. Information is given on the composition, administration, scoring, psychometric foundations, and clinical utility of nine projective techniques widely used in assessing children and adolescents.

4.15.2 OBJECTIVITY AND SUBJECTIVITY IN PERSONALITY ASSESSMENT METHODS

As a legacy of Frank's projective hypothesis, tests designated as projective methods came to be regarded as subjective in nature and hence quite different from objective methods, such as self-report inventories. This presumed subjectivity of projective methods fostered a commonplace conviction that these methods are inherently less scientific and less valid than objective methods. In actuality, however, ambiguity is a dimensional rather than a categorical characteristic of tests, and there is little basis for regarding projective methods as inherently unscientific and invalid or as sharply distinct from objective measures.

Being scientific does not inhere in the nature of a method or instrument, whether subjective or not, but only in whether it can be studied scientifically. When projective tests are used to generate personality descriptions that can be independently and reliably assessed for their accuracy, they function as a scientific procedure.

Likewise, the validity of a test inheres not in its nature, but rather in the extent to which it generates significant correlations with personality characteristics or behaviors it can identify or predict. Abundant research attests that projective methods, when properly used, can yield valid inferences (Hibbard et al., 1994; Hibbard, Hilsenroth, Hibbard, & Nash, 1995; Parker, Hanson, & Hunsley, 1988; Weiner, 1996).

Regarding sharp distinctions between projective and objective measures, the subject's task on commonly used personality tests injects considerable objectivity into many projective methods and substantial subjectivity into most objective methods. For example, responses on the Rorschach, which is the most widely used projective measure, are routinely inquired by asking subjects "Where did you see it?," which is a concrete, unambiguous request for a specific item of objective information. When subjects reply that they used the whole blot for a percept, their response is given a location choice code of W, which is an objective and unambiguous procedure on which coders achieve virtually 100% agreement. Numerous other features of how subjects choose to look at the inkblots can also be objectively coded with good inter-rater reliability, such as the percentage of responses given to the multicolored cards (affective ratio), the number of commonly given percepts reported (populars), and the kinds of objects the blots are said to resemble (people, animals, etc.) (Exner, 1991, pp. 459–460; McDowell & Acklin, 1996; Seaton & Allen, 1996).

Elements of objectivity mark the interpretation as well as the coding of many Rorschach variables. In the case of whole responses, for example, an unusual preponderance of W in a record correlates with objectively observable tendencies to attend to experience in a global fashion; a low affective radio identifies an inclination to withdraw from emotionally charged situations; a small number of popular responses correlates with behavioral manifestations of unconventionality; and numerous human percepts is associated with an active interest in people. In these and many other ways, Rorschach responses identify personality characteristics through an objective process of coding response features and relating these coded features to their known corollaries in observable behavior.

There are aspects of Rorschach interpretation that may be highly subjective, especially when inferences are drawn from the thematic imagery subjects produce when they associate to the inkblots along with describing them. Moreover, most other projective methods have not been as extensively codified as the Rorschach and depend more on qualitative than quantitative analysis. The present point is merely that the basic nature of projective methods does not preclude their being codified and interpreted to some extent along objective lines.

Turning now to aspects of subjectivity in objective methods, consider the uncertainty that characterizes many items in the most widely used objective measure of personality, the adult and adolescent forms of the Minnesota multiphasic personality inventory (MMPI-2/MMPI-A). Although MMPI-2/MMPI-A instructions to respond true or false are unambiguous and the coding of these responses is completely objective, Weiner (1993) has previously called attention to the idiography that is embedded in asking subjects to interpret such items as "I often lose my temper." Items of this type provide no benchmarks for the frequency of "often" or for what constitutes loss of temper. In many instances, consequently, responses to self-report items involve subjectivity on the part of respondents, who must define for themselves what certain terms mean before they can decide how to answer.

Subjectivity influences the interpretation as well as the response process in objective assessment. Granted, the hallmark of objective tests is an extensive array of quantified scale scores having empirically demonstrated behavioral correlates. Nevertheless, the interpretation of self-report measures in clinical practice typically goes beyond identifying known corollaries of scale scores to include consideration of complex patterns of interaction among these scores and between the test profile and aspects of a subject's clinical history, interview behavior, and performance on other tests. Some of these complex interactions have been examined empirically, such as various two- and three-point codes on the MMPI-2/MMPI-A, but many have not.

This is not to say that the MMPI-2/MMPI-A and other self-report instruments are basically subjective in nature or that they derive their utility primarily from clinical judgment. The point is merely that, just as projective instruments are not entirely subjective, self-report methods are not completely objective, but instead involve some aspects of ambiguity in how subjects respond to them and how examiners interpret them.

It is for this reason that ambiguity is not a categorical function that characterizes some tests called projective measures, but not others called objective measures. Instead, ambiguity is a dimensional function that characterizes most tests to some degree, in relation to how structured they are. Generally speaking, objective tests are more structured than projective tests and therefore less ambiguous; projective tests are generally less structured than objective tests and hence more ambiguous; and there is no sharp objective/subjective dichotomy between relatively structured and relatively unstructured instruments.

4.15.3 STRUCTURE AND AMBIGUITY IN PROJECTIVE TECHNIQUES

Projective techniques comprise inkblot methods, story-telling methods, figure drawing methods, and sentence completion methods. In addition to being less structured than objective measures, these four types of projective methods differ from each other in their degree of ambiguity and in whether their ambiguity resides mainly in their stimuli or in their instructions.

Thus in the case of the Rorschach inkblot method, subjects are asked to look at relatively ambiguous stimuli but are given fairly specific instructions to indicate what they see, where they see it, and what makes it look as it does. Story-telling methods such as the TAT involve showing subjects real pictures that are much less ambiguous than inkblots; however, by using general instructions ("Tell me a story") and open-ended questions ("What will happen next?"), examiners provide only minimal guidance in how subjects should respond. If the Rorschach instructions were "Tell me a story about this inkblot," the Rorschach would be more ambiguous and more of a projective test than it is. If the TAT instructions were "Tell me what you see here," the TAT would lose most of its ambiguity and function only barely as a projective test.

Figure drawing techniques use no stimuli at all, save a blank piece of paper, and provide little guidance to subjects, other than some instructions concerning the figures to be drawn (e.g., yourself, a family). Sentence completion methods, in common with story-telling techniques, call for subjects to provide thematic content in response to real and relatively unambiguous test stimuli. Unlike story-telling techniques, however, sentence completion methods do not ordinarily involve querying subjects about their responses or encouraging them to elaborate those that are brief or unrevealing. Thus a stem of "I AM" may be completed with "a happy person," in which case some subjectivity has been allowed to enter the response, or simply with "here," in which case only a completely objective response has been given. On balance, figure drawing techniques are the most ambiguous of projective tests and sentence completion methods the least, with inkblot and story-telling techniques in between.

These differences in ambiguity among projective methods were originally noted by Stone and Dellis (1960), who proposed "a levels hypothesis" to take practical account of this variability. According to the levels hypothesis, the degree to which a test is structured is directly related to the level of conscious awareness at which it taps personality processes. The more structured and less ambiguous a test is, the more likely it is to yield information about relatively conscious and superficial levels of personality; conversely, the less structured and more ambiguous a test is, the more likely it is to provide information about deeper levels of personality and characteristics of which subjects themselves may not be consciously aware.

Research reported by Stone and Dellis (1960) and subsequently replicated by Murstein and Wolf (1970) provided empirical support for a relationship between the ambiguity of a test and its likelihood of measuring deeper levels of personality, especially in normally functioning persons. These findings mirrored the basic conception of TAT assessment articulated by Murray (1951), who regarded the virtue of the instrument as residing not in its revelations about what subjects are able and willing to say about themselves, but in what it conveys about personality characteristics: "the patient is unwilling to tell or is unable to tell because he is unconscious of them" (p. 577).

In addition to differing from objective tests and from each other in their degree of structure and ambiguity, individual projective measures typically include both relatively objective and relatively subjective elements. As elaborated by Weiner (1977), the objective elements of projective test data involve structural features of the manner in which responses are formulated, whereas the subjective elements consist of thematic features of the imagery with which responses are embellished.

When projective test data are being interpreted objectively, structural aspects of the subject's responses, such as focusing on wholes and seeing numerous human figures on the Rorschach, are taken as being directly representative of similar behavioral tendencies in the person's life, that is, attending to experience globally and paying close attention to people. When projective test data are being interpreted subjectively, thematic imagery is taken as being indirectly symbolic of a subject's underlying needs, attitudes, conflicts, and concerns. Thus the Rorschach response of "Two girls who are really mad at each other fighting over something they both want" may identify a subject's experiencing peer or sibling rivalry, viewing social interactions as aggressive confrontations in which people are only concerned with what they can get for themselves, or feeling angry or resentful about being in such situations.

On story-telling measures, an example of a structural response feature is giving long stories, which can be objectively scored (by counting the number of words) and which provides a representative indication of inclinations to be verbose. As for subjectively interpreted features, a TAT story in which two people are described as about to separate, leaving one of them sad and lonely for the rest of his or her life, exemplifies thematic imagery that appears to symbolize concerns about suffering the loss of love objects and facing an unhappy future.

On figure drawing measures, which as previously noted are the most ambiguous of projective tests, structural features of the data are limited. Some variables, such as the size of figures drawn, how complete they are, and whether they are clothed, are objective facts that can usually be coded with good agreement. However, interpretation of such objective characteristics of figure drawings, as well as of subjective impressions of drawing qualities, is based mostly on their being symbolic rather than representative of behavior. Interpreting the way figures are drawn or placed is thus primarily thematic. For example, unusual emphasis on a particular part of the body may be interpreted as suggesting concern about functions associated with that part of the body, and a family drawing in which the self is located on one side of the page and the other family members are closely grouped on the other side of the page may be interpreted as symbolizing feelings of isolation or rejection in the family setting.

In sentence completion responses, frequent self-referencing is an example of an objectively scorable, behaviorally representative structural index of tendencies to focus attention on oneself rather than others. Consider the difference between the completions "WHAT PAINS ME is seeing how many unfortunate people there are in the world" and "WHAT PAINS ME is not being able to get the things that I want." An accumulation of the latter as opposed to the former type of response is objectively representative of self-centeredness. At the same time, the thematic content of both completions suggests in a more subjective way certain underlying concerns, such as worries about the welfare of the human race in the first instances and feelings of being personally deprived in the second.

To bring these introductory observations full circle, the opportunities that projective methods create for subjects to project aspects of themselves into their responses has frequently led to their being associated with psychoanalytic theories of personality, in the context of which the notion of projection was first elaborated. However, there is no necessary relationship between psychoanalytic theory and projective testing, nor is there any reason for clinicians who conceptualize behavior in other ways to view projective methods as incompatible with their frame of reference. The basic principle underlying projective techniques is that something can be learned about people from sampling how they respond in ambiguous situations. This principle is not prisoner to any personality theory, and its utility transcends the theoretical persuasions of individual examiners. Inferences from projective data can be couched equally well in psychodynamic, behavioral, cognitive, and humanistic terms, and the use to which these inferences can be put depends less on theoretical differences in terminology than on the nature of the assessment issues being addressed.

4.15.4 VALUE OF PROJECTIVE ASSESSMENT

Projective test data provide valuable information about how people are likely to think, feel, and act that is difficult to obtain from objective assessment procedures. This contribution of projective methods to the personality assessment process has both a conceptual and an empirical basis.

4.15.4.1 Conceptual Basis

Because of their relatively unstructured nature, projective tests measure personality characteristics in subtle and indirect ways. Even those features of projective test data that can be objectively scored and interpreted involve responses that seldom have obvious meaning. Subjects in the process of responding usually have little awareness of the interpretive significance that attaches to their seeing numerous human figures on the Rorschach, giving long stories on the TAT, drawing themselves on the far side of the page from the rest of their family, or repetitively referring to "I" in their sentence completions; indeed, they may not even be aware of having responded in these ways.

By contrast, relatively structured objective tests measure personality characteristics in direct ways that often have obvious interpretive significance. Adolescents who answer "true" to such MMPI-A statements as "At times I feel like smashing things" and "I am easily downed in an argument" will usually have a good idea of what they are indicating about themselves.

The distinction between subtle, indirect measurement of personality characteristics with projective techniques and relatively direct assessment through questionnaire methods has been formulated by McClelland, Koestner, and Weinberger (1989) in terms of differences between self-attributed and implicit motives. According to McClelland et al., self-attributed motives are measured by self-report instruments and are influenced by social incentives in a person's external environment. Implicit motives, however, are measured by such indirect techniques as story-telling procedures and are influenced by the internal pleasure derived from various activities in which a person engages.

Whereas self-attributed motives are comparatively good predictors of immediate specific responses to structured situations, McClelland et al. continue, implicit motives are comparatively good predictors of long-term trends in behavior across various types of situations. Research findings described by McClelland et al. confirmed that indirect assessments of underlying motives have greater validity for predicting long-term trends in behavior than self-report assessments of motives that people directly attribute to themselves.

More recently, Bornstein (1995) has used a metaanalysis of 97 studies of measures of dependency to demonstrate further this difference between objective and projective assessment. With respect to differential prediction, according to Bornstein, available research indicates that objectively measured dependency correlates better with symptoms and the diagnosis of dependent personality disorder than does projectively measured dependency, whereas projectively measured dependency correlates better with dependency-related behaviors.

The conceptual analysis formulated by McClelland et al. and elaborated by Bornstein has direct bearing on the contribution of projective methods to personality assessment. As previously described, projective assessment taps implicit motives and underlying personality characteristics that may not be readily apparent and may not be within a subject's conscious awareness. Because these covert motives and characteristics exert a powerful influence on long-term behavioral trends, this type of indirect measurement adds an important dimension to personality evaluations that would not be tapped in its absence.

Finally, with respect to what projective methods contribute to assessment batteries, the relative ambiguity of these methods makes them less subjective than structured instruments to influence by test-taking attitudes. This is not to say that projective methods are immune to subjects' efforts to present themselves in a positive or negative light. The relatively open-ended nature of projective testing situations and the dialogue they frequently elicit give subjects abundant opportunity to voice attitudes toward the tests, the examiner, and being examined. However, as long as subjects continue to give responses, neither their attitudes nor their expression of them is likely to prevent their projective test responses from revealing their personality characteristics. Simply put, the limited face validity of projective measures makes them more difficult to fake than objective measures, which means that they can balance a test battery to particularly good effect when self-presentation effects are of concern.

4.15.4.2 Empirical Basis

Projective measures vary in the extent to which they have been examined in well-designed research studies, and in many instances adequate empirical support for these instruments has lagged behind the uses to which clinicians sometimes put them. Nevertheless, the two most frequently used projective methods, the Rorschach and the TAT, have for the past generation been among the three most frequently studied personality assessment instruments, exceeded in this respect only by the MMPI/MMPI-2 (Butcher & Rouse, 1996). For both the Rorschach and the TAT, substantial evidence has accumulated to attest their validity for describing aspects of personality structure and dynamics and applying these descriptions in differential diagnosis and treatment planning (Abraham, Lepisto, Lewis, & Schultz, 1994; Alvarado, 1994; Bornstein, 1995; Cramer & Blatt, 1990; Exner & Andronikoff-Sanglade, 1992; Ornduff & Kelsey, 1996; Ronan, Colavito, & Hammontree, 1993; Weiner, 1996; Weiner & Exner, 1991).

Later in this chapter, specific information is presented concerning the psychometric foundations and demonstrated corollaries of the projective measures most frequently used with young people. Suffice it to say in summary at this point that these measures prove valuable in personality assessment because they add information that would otherwise be unavailable and because they withstand relatively well efforts to exaggerate or conceal.

4.15.5 UTILITY OF PROJECTIVE ASSESSMENT

Whereas the value of projective techniques lies in the previously elaborated reasons *why* they should be used in personality assessment, their utility relates to decisions concerning *when* these methods should be included in a test battery. The kinds of information provided by projective test data indicate that projective measures should be used whenever a thorough personality assessment is considered relevant to formulating a differential psychodiagnosis or recommending alternative intervention strategies. Because of their relatively unstructured nature and indirect format, projective measures balance a test battery by tapping personality characteristics at a less conscious level than relatively structured measures. Assessments lacking such balance sample personality functioning from a limited perspective that will usually fail to paint a complete picture of the individual being examined. Batteries limited solely to projective techniques are similarly imbalanced and ill-advised in comprehensive personality assessments.

The previously mentioned conceptualization of McClelland et al. (1989) bears closely on the importance of a balanced test battery in clinical assessment. McClelland and his colleagues noted that measures of self-attributed and implicit motives seldom correlate with each other and should not be expected to do so, because they are measuring different aspects of personality. Moreover, given that directly and indirectly measured motives each predict certain kinds of behavior better than the other, they concluded that "Separate measures of self-attributed and implicit motives may be combined to yield a better understanding and prediction of certain types of behavior" (p. 692).

These formulations concerning different types of measures have subsequently been elaborated and confirmed for clinical purposes with respect to relationships between the Rorschach and the MMPI. Rorschach structural variables and MMPI scales have been found to show only a few modest correlations in both adult and adolescent samples (Archer & Krishnamurthy, 1993a, 1993b). At the same time, however, apparent contradictions between Rorschach and MMPI findings have been conceptualized by Weiner (1993, 1995b) not as invalidating either instrument or challenging the incremental utility of administering them in tandem, but rather as generative data.

Specifically, Weiner argues, apparently discrepant findings between personality assessment instruments of different kinds can be generative by virtue of complementing each other. Whereas findings on two tests that concur in suggesting the same personality characteristic are confirmatory and support definite conclusions, he continues, findings that diverge raise important questions to which they may also suggest helpful answers, especially if one of the tests is a relatively structured and the other a relatively unstructured instrument.

Consider, for example, a youngster who appears depressed on the Rorschach, with a high depression index (DEPI), but does not elevate on Scale 2 or the depression content scale of the MMPI-A. This divergent finding could well provide a useful clue to the adolescent's having an underlying or emerging depression that is not yet being keenly felt or manifest in well-structured situations. Alternatively, it could be that the subject is trying to deny or repress depressive affects and cognitions, or is making a conscious decision not to report manifestations of depression that nevertheless emerge in the absence of supportive structure or are revealed when the subject is uncertain how to conceal them.

The situation described in this example is familiar to assessment psychologists, who not infrequently work with psychologically troubled adolescents who can remain reasonably comfortable and controlled in relatively structured situations but become upset and disorganized in relatively unstructured situations and who may accordingly produce a benign MMPI-A protocol and a disturbed Rorschach. In such circumstances the objective measure has not erroneously overlooked psychopathology, nor has the projective measure mistakenly exaggerated it. Instead, the two types of test have combined in complementary fashion to provide valid information concerning the subject's likelihood of behaving in a relatively adaptive or maladaptive fashion, depending on the situational context in which the behavior appears.

Similarly, subjects in some circumstances may produce a clinically unremarkable Rorschach while showing numerous elevations on the clinical and content scales of the MMPI-A. Such divergence is best understood not as error variance, but as a possible clue to the psychological stance of subjects whose degree of disturbance is minimal but who, when asked about themselves in language they can understand, want to make sure that others fully appreciate whatever problems and concerns they do have. Further illustrations of the clinical utility of divergence as well as convergence between a projective measure, such as the Rorschach and an objective measure such as the MMPI-2, are provided by Finn (1996) and Ganellen (1996).

4.15.6 APPLICABILITY OF PROJECTIVE METHODS TO CHILDREN AND ADOLESCENTS

Except for an occasional example, this chapter has thus far made no specific reference to young people. This apparent oversight is warranted by the fact that the nature of projective methods, the way in which they function, the kinds of information they provide, and the reasons for using them, are identical for persons of almost all ages. Hence the discussion of projective assessment to this point is as applicable to children and adolescents as to adults, and requires no modification or qualification as our focus now shifts specifically to young people.

Indeed, assessors who have learned to interpret projective test data provided by adults do not need to learn any new ways of working with the data should they begin to examine children and adolescents. By and large, the basic interpretive conclusions and hypotheses that attach to projective test variables apply regardless of the age of the subject. Whether they are age 8, 18, or 80, subjects who see numerous human figures on the Rorschach are likely to be quite interested in people; those who give long TAT stories are likely to be verbose; those who refer frequently to themselves in sentence completions are likely to be self-centered; and those who draw grotesquely distorted human figures probably harbor some disturbing concerns about their own nature or that of other people.

However, in order to determine the implications of these and other personality characteristics suggested by projective test data, examiners assessing young people must take into account normative developmental expectations. For example, the data of developmental psychology indicate that children are more self-centered than adults, and subsequently become increasingly aware of and concerned about the needs of others as they grow through adolescence and approach maturity. Accordingly, test data that identify a high degree of self-centeredness may imply maladaptive narcissistic personality traits in an adult, but reflect normal development and adaptation in a child; conversely, minimal self-centeredness may indicate altruism and good adjustment in an adult but suggest deviant development and low self-esteem in a child.

Developmental psychology similarly provides some normative expectations for how children are likely to make drawings. Preschool age children commonly draw with what is called "intellectual realism," which means that they draw what they know to be there regardless of whether it would actually be visible. Thus, in x-ray fashion, young children often draw transparencies, such as people who are visible through walls (Di Leo, 1983). At about age 7 or 8, this intellectual realism gradually gives way to "visual realism," in which what is drawn resembles what realistically can be seen. Di Leo (1983, p. 38) observes that this developmental shift mirrors a metamorphosis in thinking from an egocentric to an increasingly objective view of the world. Hence a human figure drawing by a preschool child showing a belly button through clothing is much less likely to imply maladaptive functioning that the same drawing done by an adolescent.

As these examples indicate, familiarity with and adequate attention to normative expectation hold the key to valid and useful applications of projective methods in the assessment of young people. Ideally, projective methods manuals should include normative reference data that delineate quantitative as well as qualitative expectations for such developmental phenomena as maturational changes in self-centeredness. Regrettably, even though numerous projective test variables have been quantified in various ways, little progress has been made in generating age-graded norms for them.

The main exception to this dearth of normative developmental data for projective techniques is the Rorschach. Developmental trends in Rorschach responses from early childhood through adolescence were initially charted many years ago by Ames and her colleagues (Ames, Metraux, Rodell, & Walker, 1974; Ames Metraux, & Walker, 1971). More recently, the Rorschach comprehensive system has provided reference data for each of its codified variables on samples of approximately 100 nonpatient young people at each age from 5 to 16 (Exner & Weiner, 1995, chap. 3).

Aside from identifying needs for further research, an analysis of available data can guide clinicians in choosing which projective methods to include in a battery for assessing a young person's functioning. The more thorough and reliable the normative developmental data available for the instrument, the better the choice it will make. Similarly, the better established an instrument's correlates are in relation to behaviors that are central to the purpose of an assessment, the more reason there is to include it. Thus an instrument that has been demonstrated to be particularly helpful in identifying youthful depression may be a good choice in one case, whereas an instrument known to be especially sensitive in revealing family dynamics may be a good choice in another case.

Similarly, available empirical data and reported clinical experience should be drawn on to determine whether a particular instrument is likely to yield useful information concerning the personality functioning of individuals at certain ages. Thus the children's apperception test (CAT) depicting animal figures may be a more effective story-telling measure for a young child than the TAT, but certainly not for an adolescent (Bellak, 1993, p. 237).

As these observations indicate, projective methods provide sound clinical data only if they are employed in appropriate ways. First, examiners should have recourse to standardized procedures for administering and scoring any test they use. Lack of such standard methodology compromises the value of the data obtained, and inattention to standardized methods by examiners who opt instead for personalized approaches to administration and scoring is clinically disadvantageous and professionally questionable.

Second, clinical interpretations should be derived from test variables with demonstrated reliability and validity. Inadequate psychometric foundations limit the use to which test data can be put, and examiners who draw conclusions in the absence of supporting empirical evidence, without framing such conclusions as speculative hypotheses, are doing their patients and their methods a disservice. Third, the adequacy of projective assessment of young people will be limited in the absence of normative reference data for test responses of both adjusted and maladjusted children and adolescents and for developmental changes in these responses over time.

This chapter continues with reviews of the major inkblot, story telling, figure drawing, and sentence completion methods used in assessing young people. The composition, administration, and scoring of each of these measures are described; what is known about their reliability, validity, and normative database is reported; and the clinical purposes they are likely to serve are discussed. The specific measures reviewed are selected primarily on the basis of their emphasis and frequency of use in clinical and school settings, as reported in surveys by Archer, Imhof, Maruish, and Piotrowski (1991), Elbert and Holden (1987), Hutton, Dubes, and Muir (1992), Kennedy, Faust, Willis, and Piotrowski (1994), Piotrowski and Keller (1989), Stinnett, Havey, and Oehler-Stinnett (1994), and Watkins, Campbell, Nieberding, and Hallmark (1995).

4.15.7 REVIEW OF PROJECTIVE ASSESSMENT METHODS

4.15.7.1 Rorschach Inkblot Method

The Rorschach inkblot method comprises 10 cards that are inked in shades of black and gray (five cards); black, gray, and red (two cards); and various pastel colors (three cards). The cards are reproduced in standard fashion, but the inkblot stimuli were originally designed at random and do not portray any specific objects (Rorschach, 1942). When subjects respond to the Rorschach, they draw on the shape, shading, and color of the blots to form impressions of what they might be, and in so doing they treat the instrument as a cognitive–perceptual task (e.g., "It looks like a bat, because it's got a body here and wings here and it's black"). In addition, subjects frequently elaborate their responses beyond the stimulus properties of the blots, and in so doing they treat the instrument as an associational task (e.g., "This bird is flying around looking for something to eat").

The cognitive–perceptual aspects of responses constitute structural data in Rorschach assessment and provide representative indications of the resources and coping style that a person generally brings to bear in problem-solving situations. The associational aspects of responses constitute thematic data in Rorschach assessment and provide symbolic clues to the underlying needs, attitudes, conflicts, and concerns that are likely to influence a person's actions and state of mind. The basic nature of the Rorschach in these respects is discussed further by Exner and Weiner (1995, chap. 1) and Weiner (1986, 1994).

4.15.7.1.1 Administration and scoring

The Rorschach is introduced by telling subjects that the inkblots they are about to see are not anything in particular, but that people see many different things in them and that their task will be to indicate what the inkblots look like to them. The 10 cards are then given to subjects one at a time with the instruction "What might this be?" Requests for structure (e.g., "Can I turn the card?") are deflected back to the subject (e.g., "It's up to you"; "Any way you like"). The unguided responses to the 10 cards constitute the free association phase of the administration, following which there is an inquiry phase in which the examiner reads back each response and asks subjects where they saw it and what made it look as it did. The purpose of the inquiry is to facilitate coding of the structural features of the responses, and associations during this phase are not requested or encouraged. Responses are recorded verbatim, however, and the content of any spontaneous thematic elaborations is carefully noted.

Numerous approaches to codifying Rorschach responses have emerged during the long history of this instrument. However, for many years the comprehensive system of Exner (1993) has been by far the most widely used and researched (Piotrowski, 1996). Rorschach responses are coded in the comprehensive system for various aspects of where percepts are seen (location), why they look as they do (determinants), what they consist of (content), how commonly they occur (form level and populars), and whether they involve pairs of objects, organization of parts, or special kinds of elaborations, such as cooperative or aggressive interaction. These codes are than tallied and combined in various ways to yield a large number of indices, ratios, and percentages that guide the interpretive process, as elaborated in detail by Exner (1991, chaps 5–10).

4.15.7.1.2 Psychometric foundations

The psychometric foundations of an assessment instrument comprise the extent to which it can demonstrate adequate interscorer agreement, reliable measurement, valid correlates, and a representative normative database. The Rorschach inkblot method, as already indicated in part by examples used earlier in the chapter, rests on a solid psychometric basis. Interscorer agreement for the types of variables coded in the comprehensive system typically ranges from 80% to 100%. The reliability of Rorschach data has been demonstrated in a series of retest studies conducted over intervals ranging from seven days to three years and involving child, adolescent, and adult subjects. Most of the core variables associated with trait dimensions of personality show stability coefficients greater than 0.80 in these studies, and some, including the affective ratio and the egocentricity index, consistently hover around 0.90 (Exner, 1991, pp. 459–460; Exner & Weiner, 1995, pp. 21–27; McDowell & Acklin, 1996; Weiner, 1997).

The validity of Rorschach assessment was confirmed in a series of metaanalytic studies that led Parker, Hanson, and Hunsley (1988) to conclude that the Rorschach meets usual psychometric standards for validity and is comparable to the MMPI in this respect. Specifically, Parker et al. used the effect sizes reported in 411 studies to derive population estimates of convergent validity of 0.41 for the Rorschach and 0.46 for the MMPI. Subsequent further confirmations of the validity of this instrument are noted by Weiner (1996).

With respect to its normative database, available information for the comprehensive system includes data on 700 nonpatient adults demographically representative of the 1980 US census, 1390 nonpatient children and adolescents age 5 to 16, and large samples of schizophrenic, depressed, and character disordered patients (Exner, 1993, chap. 12). In addition, longitudinal data reported by Exner, Thomas, and Mason (1985) on a group of young people tested every two years from age 8 to 16 provide useful reference information concerning developmental stability and change in Rorschach variables during childhood and adolescence.

As implied by the nature of the normative data, the Rorschach comprehensive system is applicable to young people from age five. Preschool age children have ordinarily not yet matured sufficiently to deal with the cognitive–perceptual aspects of the Rorschach situation in ways that lend themselves to the codification that is central to the comprehensive system interpretive process. An unusually mature four-year-old might on occasion produce a useful record, and immature five- and six-year-olds may produce records that have limited interpretive significance within the framework of the comprehensive system. Working within other frameworks, Ames et al. (1974) discuss and provide some normative findings for Rorschach responses of young children, and Leichtman (1996) has recently presented a developmental rationale for deriving information from the records of preschoolers.

4.15.7.1.3 Clinical utility

In common with projective techniques in general, the Rorschach serves clinical purposes primarily as a result of the information it provides about the structure and dynamics of personality functioning. With respect to personality structure, the Rorschach has proved especially helpful in identifying and quantifying states of subjectively felt distress that combine elements of anxiety and depression and in reflecting trait dimensions of how people typically think, process information, handle emotions, manage stress, feel about themselves, and relate to others. Regarding personality dynamics, the thematic content of Rorschach responses, as previously noted, is often quite revealing of underlying needs, attitudes, conflicts, and concerns that influence how people are likely to think, feel, and act at particular points in time and in particular situations.

In addition, Rorschach data can frequently contribute to differential diagnosis in clinical settings. The comprehensive system provides indices for schizophrenia and depression (DEPI) that can help to identify these conditions in children and adolescents as well as in adults; for basic deficits in coping capacity that point to developmental arrest in young people; and for numerous features of conduct and anxiety and/or withdrawal disorders (Exner & Weiner, 1995, chaps 5–8; Weiner, 1986). Rorschach findings have also demonstrated considerable clinical utility in the treatment process by clarifying treatment targets, identifying potential obstacles to progress in therapy, and providing a basis for evaluating treatment change and outcome (Abraham et al., 1994; Weiner, 1994).

4.15.7.2 Thematic Apperception Test

The most widely known and used story telling technique is the TAT. It was developed by Morgan and Murray (1935) in the belief that the content of imagined stories would provide clues to the underlying dynamics of a subject's interpersonal relationships and self-attitudes. As elaborated by Murray (1943, 1971) and Bellak (1993, chap. 4), TAT data are expected to reveal the hierarchy of a person's needs and the nature of his or her dominant emotions and conflicts.

The TAT stimuli comprise 19 black-and-white illustrations of people or scenes and one blank card. The cards are intended for use with persons age five or older of both genders, and for nine of the cards there are alternate versions for use with adult and child/adolescent males and with adult and child/adolescent females. Because of the time required to administer the full set of TAT cards, examiners typically select a subset of 8–12 cards that they anticipate will elicit themes relevant to the assessment issues in a particular case. The themes usually elicited by the individual cards and the selection of subsets suited for children and adolescents are reviewed by Bellak (1993, chap. 3), Dana (1985), and Obrzut and Boliek (1986). Regrettably with respect to standardization, however, there are no specific short forms of the instrument, and how many and which cards are typically chosen vary from one examiner to another and from one examination to the next.

4.15.7.3 Administration and scoring

The TAT cards are given to subjects one at a time with instructions to make up a story for each picture that includes (i) what is happening at the moment, (ii) what the characters are thinking and feeling, (iii) what led up to the situation, and (iv) what the outcome will be. The narrated stories are recorded verbatim by the examiner.

Murray (1943) originally proposed a scoring scheme in which each TAT story is rated for the presence and strength of a long list of needs that are being experienced by the central figure in the story and presses that are being exerted by the environment. This scoring system proved too elaborate and time consuming for clinical work, and numerous alternative approaches to clinical interpretation were subsequently developed for the instrument. As reviewed by Chandler (1990), Murstein (1963), and Vane (1981), some of these interpretive approaches, like Murray's, have consisted of formal quantitative ratings of story characteristics. However, most interpretive approaches have eschewed quantitative scoring in favor of qualitative analyses of story content, and no scoring system has gained widespread use either clinically or in research studies.

The most commonly employed methods of interpreting the TAT in clinical practice appear to be variations of an "inspection technique" proposed by Bellak (1993, chap. 4). This technique consists simply of reading through subjects' stories to identify repetitive themes and recurring elements that appear to fall together in meaningful ways. Because this approach lacks any quantification and rests on the capacity of individual examiners to relate story themes and elements to aspects of personality functioning, Dana (1985) was moved to observe that "TAT interpretation has become a clinical art form" (p. 90).

Bellak's influential approach stresses 10 aspects of a story, each of which is taken to have implications for how subjects view and are likely to deal with interpersonal events and what they anticipate the future to hold for them. These include the main theme of the story, the identity of the central figure or hero, the main needs of the hero, the way in which the environment is conceived, the identity and intentions of other figures in the story, the nature of any anxiety or other affect that is being experienced, the nature of any conflict that is described or suggested, the ways in which conflicts and fears are defended against, the ways in which misbehavior is punished, and the level of ego integration.

With respect to research studies, the most productive utilization of the TAT has derived from quantitative scoring systems developed by McClelland, Atkinson, and their colleagues to measure needs for achievement, affiliation, and power (Atkinson & Feather, 1966; McClelland, Atkinson, Clark, & Lowell, 1953). Although scoring for achievement, affiliation, and power motivation has had little clinical impact, other schemes for coding specific personality characteristics reflected in TAT thematic content have subsequently emerged. These include scales for level of ego development (Sutton & Swenson, 1983), preferred defense mechanisms (Cramer, 1987), quality of interpersonal affect (Thomas & Dudek, 1985), problem-solving style (Ronan et al., 1993), and object relations capacities (Westen, Lohr, Silk, Kerber, & Goodrich, 1985).

Particularly promising among these is the use of the TAT to assess aspects of object relatedness through the Westen et al. (1985) measure, known as the social cognition and object relations scale (SCORS). The SCORS provides quantitative indices of the affective tone subjects ascribe to relationships, their capacity for emotional investment in relationships and social standards, their understanding of social causality, and the complexity of their representations of people. By including ratings of subjects along dimensions of maturity as well as normality/pathology, the SCORS is proving especially relevant to the assessment of young people (Westen et al., 1991).

4.15.7.3.1 Psychometric foundations

Efforts to demonstrate the reliability and validity of global approaches to interpreting the TAT have been handicapped by the previously noted proliferation of scoring systems, by clinicians' preferences for a strictly qualitative and uncoded approach to the data, and by enormous variation in how the test is administered, including which subset of cards is selected for use. Because of this long-standing lack of standardization, there has been little opportunity for systematic accumulation of data bearing on the reliability and validity of the TAT in general, nor has it been possible to develop any substantial normative database.

Accordingly, for both inspection techniques and overall scoring systems developed in the tradition of Murray, the psychometric literature on the TAT is generally acknowledged to comprise a mix of positive and negative findings that cannot easily be compared with one another. Hence, despite the widespread use of inspection techniques in clinical practice, neither these nor other global approaches have been demonstrated to show adequate psychometric properties.

However, research studies with TAT scales developed to measure specific personality characteristics have demonstrated that the instrument can generate reliable and valid findings when it is used in a standardized manner. The previously mentioned scales of Cramer (1987) and Westen et al. (1985) are cases in point. Cramer's scale reliably identifies three major mechanisms of defense—denial, projection, and identification—and has shown valid corollaries in changes observed in patients undergoing psychotherapy (Cramer & Blatt, 1990). The Westen et al. SCORS has been found to provide reliable identification of developmental variables related to disturbed object relations in children and, as already mentioned, is therefore especially relevant to the assessment of young people. Validation studies with SCORS have involved psychiatrically disturbed, borderline, physically abused, and sexually abused young people (Freedenfeld, Ornduff, & Kelsey, 1995; Ornduff, Freedenfeld, Kelsey, & Critelli, 1994; Westen, Ludolph, Block, Wixom, & Wiss, 1990; Westen, Ludolph, Lerner, Ruffins, & Wiss, 1990).

4.15.7.3.2 Clinical utility

The clinical utility of the TAT lies mainly in its potential for elucidating dynamic aspects of personality functioning, particularly with respect to the feelings and attitudes that subjects hold towards other people, themselves, and possible turns of fortune in their lives for better or worse. Based on the assumption that children and adolescents identify with the central figures in their TAT stories and project fantasies and realities regarding their own lives into the events and circumstances they describe, the obtained data can shed light on a broad range of underlying influences on how young people are likely to think, feel, and act.

As previously noted in commenting on the research of McClelland et al. (1989), the implicit types of motives measured by the TAT are more likely to correlate with persistent dispositions to behave in certain ways rather than with immediate actions or symptom formation. Accordingly, TAT findings will usually not add very much to structural diagnosis of adjustment problems in young people, but they can be extremely helpful in suggesting possible dynamic origins of adjustment problems. In this regard, the psychometrically sound SCORS may be a useful scale to include in forensic assessment batteries when issues of custody or adoption are being addressed. This TAT scale can frequently assist examiners in grasping a young person's representations of people and his or her capacities for emotional investment in relationships.

The thematic content of TAT stories has additional potential to facilitate planning and conducting psychotherapy with young people, particularly with respect to identifying treatment targets and monitoring progress in therapy. The TAT can also be used in treatment as a play therapy tool, as in Gardner's (1971) story telling technique. For example, after a youngster has told TAT stories, the therapist and child can act out the stories in play, or the therapist can create stories to the same picture stimuli for comparisons with the child's stories. Hoffman and Kupperman (1990) describe such an intervention with a 13-year-old boy in which both therapists wrote stories to the same TAT cards to which the patient had responded. As it turned out, Hoffman's stories emphasized the main character's maladaptive coping mechanisms, whereas Kupperman's stories emphasized positive and healthy aspects of the central character's coping capacities. Over a number of sessions, this boy and his therapist engaged in discussions concerning whose version of the story was most accurate.

4.15.7.4 Children's Apperception Test

Consistent with the purpose of the TAT, Bellak (1993, chap. 13) developed the CAT to facilitate understanding of personality processes in children, including their "dynamic way of reacting to and handling the problems of growth" (Bellak & Siegel, 1989, p. 102). The CAT pictures were designed to elicit fantasies about aggression, sibling rivalry, fears of being alone at night, attitudes toward parental figures, and eating problems.

The CAT-Animal (CAT-A) form, originally published in 1949 and designed for children 3–10 years old, consists of 10 pictures depicting animals in human situations. The use of animal figures was based on the assumption that young children identify more readily with animals than with people and will accordingly tell more meaningful stories about animal than human figures. Moreover, according to Bellak (1993, chap. 13), the use of animal figures makes the CAT-A a culture-free test that is equally applicable to Caucasian, African-American, and other minority group youngsters as well as to children from different countries, except where there is little familiarity with some of the inanimate objects depicted, such as bicycles.

There is also a human form of the CAT (the CAT-H) that was developed by Bellak and Hurvich (1966) in response to criticism of the assumption that children identify more easily with animal than with human figures. Studies reviewed by Bellak and Hurvich indicate little difference in stimulus value between the original CAT-A and the CAT-H, in which human figures are substituted for the animals in the CAT-A scenes. However, the CAT-H does not appear ever to have become much used in clinical practice.

4.15.7.4.1 Administration and scoring

Children being administered the CAT are told that they are going to take part in a game in which they will tell stories about pictures. Subjects who appear to regard the CAT as a test are informed that it is not the type of test in which they will be graded for correct or incorrect answers. Standard procedures call for all 10 CAT pictures to be administered in numerical order, from Card 1 to Card 10. Children are told to narrate what the animals are doing in the pictured scenes and are asked at appropriate points to say what went on previously and what will happen next. The examiner encourages and prompts the subject as necessary but avoids being suggestive or asking leading questions. Examiners may also query each story by asking the child to elaborate specific points such as the ages of characters and why they were given particular names.

In clinical work the CAT is typically interpreted along the lines proposed by Bellak for the TAT, that is, with an inspection technique used to form qualitative impressions of various dimensions of the subject's personality functioning (Bellak, 1993, chap. 14). There is an alternative but rarely used quantitative approach developed by Haworth (1965), called the schedule of adaptive mechanisms, in which CAT responses are rated numerically for the degree of adaptability or disturbance they reflect. Haworth also stressed the importance of recognizing that young children are highly reactive to the immediate circumstances in their lives and less likely than adolescents or adults to have formed well-established personality traits. She accordingly emphasized careful interpretation of CAT responses in the context of adequate information concerning subjects' home situation and the nature of any recent or impending crises in their lives.

4.15.7.4.2 Psychometric foundations

There has regrettably been little accumulation of empirical data bearing on the reliability and validity of the CAT. The widespread use of Bellak's qualitative inspection technique in CAT interpretation and a corresponding lack of quantification have precluded examination of the instrument's psychometric foundations. Although it has sometimes been suggested that the idiographic nature of CAT as well as TAT data makes traditional psychometric criteria difficult to apply or even irrelevant, there is nothing in the nature of the data generated by story telling techniques that prevents their being reliably coded for various types of feelings, motives, attitudes, and capacities that can in turn be validated against meaningful correlates. The previously noted development of psychometrically sound TAT scales for such specific aspects of personality as achievement motivation and social cognition proves the point that clinical interpretation of stories can go beyond being an art form and attain respectability as a scientific procedure as well.

Regarding what research is available concerning the CAT, Bellak (1993, chap. 16) provides a review of studies comparing the responses typical of children at different ages and examining special features in the stories of maladjusted, schizophrenic, speech disordered, retarded, brain-damaged, and chronically ill children. Almost all of these studies date from the 1950s, however, and none provides an adequate basis for developing any formal normative standards or diagnostic guidelines for the instrument.

4.15.7.4.3 Clinical utility

As in the case of the TAT, the CAT is useful in clinical assessment primarily as a source of hypotheses concerning subjects' personality dynamics, particularly with respect to how they view themselves and other important people in their lives, the nature of their hopes and fears, and what they expect will happen to them. Although not suitable for adolescents, the CAT is more useful than the TAT in work with younger children, who are likely to relate more easily to the familiar situations and youthful figures depicted in the CAT illustrations than to the primarily adult figures and unpopulated scenes shown in the TAT.

Like the TAT, the CAT may also contribute to treatment planning, by suggesting areas of concern on which to focus in the therapy, and it may itself serve as a play technique. In diagnostic assessments, however, hypotheses generated by this instrument require support from other data prior to being addressed to questions that necessitate empirical decision making.

4.15.7.5 Roberts Apperception Test for Children

The Roberts apperception test for children (RATC) is intended for use with young people of ages 6–15 and was designed to improve on the TAT and CAT by presenting familiar stimuli and employing a standardized scoring system (McArthur & Roberts, 1990).

Instead of illustrations primarily of adults, such as those used in the TAT, or illustrations of animals, as used in the CAT, the RATC primarily portrays child and adolescent figures engaged in everyday interactions, including scenes of parental affection, disagreement, school and peer relationships, and observation of nudity. There are 27 RATC cards, 11 of which are alternate versions for male or female subjects. There is an addition an alternate set of cards portraying African-American individuals in similar scenes.

4.15.7.5.1 Administration and scoring

The standard 16 cards that compose the RATC are administered individually in numerical order, using male or female versions as appropriate. Subjects are instructed to make up a story about each picture and to tell what is happening in the picture, what led up to the scene, how the story ends, and what the people are talking about and feeling. Responses are recorded verbatim.

If subjects tell an incomplete story or omit certain aspects, such as how the characters are feeling, additional inquiry may be used to help teach them to give scorable responses. This inquiry may be used liberally with the first two cards but not thereafter, which means that responses on cards 3 through 16 may at times have limited scorable data. The possibility of limited scorable data is the price to be paid for maintaining careful standardization of the RATC procedure. McArthur and Roberts sanction deviations from the standard procedures only in specific instances, such as the examination of severely disturbed children. When standard procedures are not or cannot be followed, they recommend considerable caution in using the scoring procedures.

The scoring system for the RATC consists mainly of coding the content of each story for the presence or absence of 13 profile scales that have implications for personality characteristics. Eight of these are adaptive scales that relate to thematic indications of reliance on others, giving support to others, supporting oneself, limit-setting by authority figures, identification of problem situations, and resolving problems in unrealistic, constructive, or particularly insightful ways. The other five are clinical scales that pertain to thematic manifestations of anxiety, aggression, depression, experiences of rejection, and inability to resolve problems. The test manual provides guidelines and examples that promote reliable scoring of each of these scales.

To facilitate interpretation of the data, the raw scores for each of the 13 profile dimensions are summed over the 16 cards and then plotted on a normatively scaled profile form to yield a visual representation of the data, much in the manner of an MMPI-A profile. The interpretive yield of the data is further enriched by use of an interpersonal matrix, which consists of a tabular representation of the frequency of convergence between particular scales and the figures identified (e.g., cooccurrence of themes of reliance on others with description of interaction with a maternal figure).

4.15.7.5.2 Psychometric foundations

As with the careful coding of specific variables on the TAT, the development of standardized administration and scoring procedures for the RATC has demonstrated that story telling projective methods can achieve psychometric respectability. McArthur and Roberts (1990) report inter-rater agreement ranging from 0.80 to 0.93 in the scoring of the various dimensions in their system and split-half reliabilities ranging from 0.44 to 0.86 on their profile scales, with half of these scales showing reliability coefficients of 0.73 or higher. The adaptive scales appear to work better in this regard than the clinical scales: only one of the five clinical scales (inability to resolve problems) shows a split-half reliability greater than 0.55, whereas all but one of the eight adaptive scales (reliance on others) shows a split-half reliability above 0.60.

Validity studies conducted with 200 nonpatient and 200 outpatient youngsters aged 6–15 indicate that subjects generally tell stories that fit the expectations for the cards for example, that a card intended to depict parental affection typically elicits stories involving affection. In addition to thus showing content validity, the RATC profiles have been found to distinguish between well-adjusted and clinic youngsters, to be more resistant to efforts at manipulation than self-report measures, and to correlate well with a behavior problem checklist completed by subjects' parents (McArthur & Roberts, 1990; Worchel, Rae, Olson, & Crowley, 1992). Significantly, however, in the comparisons between well-adjusted and clinic youngsters, significant differences were found on all eight of the adaptive scales and on two of the five clinical scales, but not on the clinical scales for anxiety, aggression, and depression.

With respect to its normative database, the RATC manual provides the mean and standard deviation for each of the profile scales for 200 nonpatient youngsters divided by gender and by four age categories (6–7, 8–9, 10–12, and 13–15).

4.15.7.5.3 Clinical utility

Similar to the TAT, CAT, and other storytelling measures, the RATC contributes to personality assessment of young people primarily by casting light on their underlying attitudes and concerns. Although the measure includes specifically designated clinical scales that might be expected to assist in clinical diagnosis as well as dynamic analysis of a youngster's personality functioning, its clinical scales as noted appear less reliable than its adaptive scales and less capable of discriminating between patient and nonpatient populations.

The RATC is especially valuable to clinicians as well as researchers by virtue of its careful standardization and adequate psychometric properties. Aside from facilitating the interpretive process and providing the basis for systematic accumulation of data, these features of the instrument make it particularly attractive to examiners conducting forensic evaluations. Having used the RATC in their projective assessment of a child or adolescent, rather than the TAT or CAT, psychologists will be better prepared to justify their procedures and conclusions when giving testimony as an expert witness.

However, examiners may sometimes question whether the information they get from the RATC warrants the amount of time required to administer it, which in our experience approximates an hour on the average. For some young children, moreover, there may be difficulties in sustaining their investment in the task. There is no short form of the RATC to use and no shortcut, such as selecting just a few cards to use or discontinuing a protracted administration before giving all 16 cards. Doing so eliminates the standardization of the instrument and prevents any meaningful scoring or comparisons with normative data, which means that the test loses its advantage over a TAT or CAT interpreted by inspection. Our view in this matter is that the RATC warrants the time required to administer and score it in the standardized manner and, more generally, that psychologists should if at all possible take whatever time is necessary to use standardized instruments when they are available.

The alternate form of the RATC involving African-American figures may prove useful in assessing African-American young people. However, there are as yet no data establishing the reliability and validity of this alternate form, nor have any representative normative data been published for it. Hence the RATC should be used cautiously in multicultural assessments, for which at present the most promising instrument is Tell-me-a-story.

4.15.7.6 Tell-me-a-story

The Tell-me-a-story (TEMAS) was designed as a multicultural story-telling test based on the concept that personality development occurs within a sociocultural system in which individuals internalize the cultural values of their family and society (Costantino, Malgady, & Rogler, 1988). The TEMAS is intended for use with African-American, Hispanic, and Caucasian children and adolescents aged 5–18 and comes in two parallel sets, one for minority and the other for nonminority youngsters. The two sets feature either predominantly Hispanic and African-American characters or predominantly nonminority characters all shown in urban environments. Each set comprises 23 cards, 11 of which have alternate versions for males and females and one of which has alternate versions for children and adolescents.

As a distinctive feature of the TEMAS, many of the pictures portray a split scene showing contrasting or conflicting intrapersonal and interpersonal situations that require some resolution, much in the manner of Kohlberg's (1976) moral dilemma stories. For example, one side of a scene may depict apparent delay of gratification, and the other side an inability to delay gratification. How subjects resolve this conflict in their stories speaks to the adaptiveness of their personality functioning and their stage of moral development.

The TEMAS provides quantitative scales for measuring the adequacy of subjects' adaptation with respect to nine aspects of personality functioning: interpersonal relations, aggression, anxiety/depression, achievement motivation, delay of gratification, self-concept, sexual identity, moral judgment, and reality testing. There are also quantitative scales for four cognitive functions related to how individual process information (reaction time, total time, fluency as reflected in the number of words used in a story, and omissions of relevant visual details) and for four affective functions as indicated by mood states attributed to the main characters in a story (happy, sad, angry, and fearful). These quantitative scales are supplemented by several qualitative indicators used to describe various other characteristics of the stories.

As stressed by Costantino, Malgady, and Rogler (1988), the TEMAS was developed to overcome limitations of traditional thematic apperception tests and differs from the TAT in several significant ways. These include a focus on interpersonal relationships rather than on intrapsychic dynamics; the use of personally relevant and culturally sensitive stimuli that emphasize meaning rather than ambiguity; the representation of both positive and negative poles of emotions, cognitions, and interpersonal functions, as opposed to the heavy weighting of the TAT stimuli with representations of depression, gloom, anger, and hostility; and the introduction of the joint depiction of contrasting circumstances to elicit expressions of conflict resolution and moral judgment.

4.15.7.6.1 Administration and scoring

Subjects are administered either the minority or nonminority form of the TEMAS, and examiners can choose between a long form, which comprises all 23 cards and requires approximately two hours to administer, and a standard short form, which consists of nine cards and requires one hour to give. In keeping with generally recommended practice in multicultural assessment (Dana, 1993, chap. 6, 1996), young people should be tested in their primary language, and those who are bilingual should be tested by a similarly bilingual examiner. Subjects are instructed to tell a complete story about each picture that indicates what is happening now, what happened before, and what will happen in the future. These instructions may be repeated as often as necessary and supplemented with structured inquiries to elicit information concerning who and where the characters are and what they are thinking and feeling.

The TEMAS is scored by rating stories for the presence of the various cognitive and affective functions and on a four-point scale for the level of adjustment reflected in thematic indications of the personality functions. The resulting scores are then totaled and translated into normalized T scores that are graphed to provide a readily interpretable visual profile. The TEMAS manual provides detailed guidelines and case examples to illustrate these scoring procedures.

4.15.7.6.2 Psychometric foundations

As described in the test manual (Costantino, Malgady, & Rogler, 1988), the TEMAS was carefully developed and standardized over several years prior to its publication. Unfortunately, except for continued work by the test's authors, much of it in the form of paper presentations, there has been little published research concerning the psychometric adequacy of the instrument. On balance, however, the data provided in the test manual appear to indicate a promising beginning in demonstrating its soundness.

With respect to inter-rater agreement, studies with Hispanic, African-American, and Caucasian subjects have indicated that both the minority and nonminority versions of TEMAS can be scored reliably, with agreements between trained examiners generally ranging from 75% to 95% across the various scales. Regarding issues of reliability, on the long form of the TEMAS 11 of the 17 personality, cognitive, and affective scales showed internal consistency (alpha) correlations of 0.74 or higher in the standardization data, and the median for all 17 was 0.83. Internal consistency was lower on the short form, with a median of 0.68. The internal consistency data for the short form must be considered preliminary, however, because in this analysis the short form scores were extracted from the protocols of subjects who had in fact completed the long form, rather than from actual administration of the short form. In an assessment of its retest reliability, the short form was administered twice to 51 behavior problem children over an 18 week interval. Very little stability over time was demonstrated in this study. Costantino, Malgady, and Rogler (1988) suggest several plausible explanations for this disappointing result, such as the narrow range of scores among the subjects. Nevertheless, test–retest reliability remains to be demonstrated for both the short and long forms of the instrument.

Turning to the validity of the TEMAS, ratings by psychologists of the types of personality functions pulled by the stimulus pictures have indicated good agreement with the intent in designing them, thus attesting that the test measures what it purports to measure. In terms of its criterion validity, the TEMAS has been found in several studies to discriminate between patient and nonpatient youngsters in Hispanic and African-American as well as Caucasian samples, and to accomplish this distinction in inner city as well as middle-class settings (Costantino, Malgady, Bailey, & Colon-Malgady, 1989; Costantino, Malgady, Colon-Malgady, & Bailey, 1992; Costantino, Malgady, Rogler, & Tsui, 1988). The TEMAS has not demonstrated any capacity to differentiate specific kinds of disorders, but there is some evidence to suggest that certain story characteristics, including the omission of main characters or events and failure to notice a conflict in the picture (due to lack of attention), may be sensitive to the presence of attention deficit hyperactivity disorder (Costantino, Colon-Malgady, Malgady, & Perez, 1991).

Initial studies reported in the TEMAS manual indicate further that many of its scales correlate significantly with behavior ratings by subjects' mothers and teachers and with behavioral observations of their inclinations toward aggressive or disruptive behavior and their capacities for self-confidence and delay of gratification. Preliminary data indicate further that TEMAS profiles of young people prior to their entering therapy can significantly predict aspects of their treatment outcome.

The TEMAS standardization sample comprised 281 male and 361 female youngsters from the New York City area who ranged in age from 5 to 13 years. This sample of 642 children and adolescents included groups of Caucasian, African-American, Puerto Rican, and other Hispanic subjects from predominantly lower- and middle-income families. The test manual lists the mean and standard deviation for each scale by gender and ethnicity for the age groups 5–7, 8–10, and 11–13.

4.15.7.6.3 Clinical utility

The TEMAS brings to clinical assessments the distinct advantages of a well conceptualized and quantitatively standardized story-telling technique that is also culturally sensitive and normed for minority groups of young people. As in the case of the RATC, its coded scales and profile graphs facilitate interpretation and provide the type of documentation that typically proves valuable in forensic cases. Moreover, this measure stands alone as a story-telling test proved applicable in the assessment of African-American and Hispanic children and adolescents. The TEMAS accordingly merits serious consideration for inclusion in a test battery for evaluating personality functioning in young people, especially if they come from an urban minority background and if there are forensic issues in the case.

At this stage in its development, however, the TEMAS has some drawbacks that examiners should keep in mind. First, although it appears to be useful for assessing level of adjustment and incorporation of societal norms among both minority and nonminority youth, TEMAS does not provide the breadth of information concerning specific types of concerns and relationships that emerge from TAT, CAT, and RATC analyses. Second, the normative data available thus far are limited to 5–13-year-old city dwellers and thus do not provide a psychometric basis for drawing conclusions about adolescents aged 14–18, or suburban and rural dwelling youngsters. Third, the length of time (two hours) required to administer the 23 card long-form of the test is often impractical in clinical evaluations. The nine card short-form is an attractive alternative but, as noted, adequate reliability has not yet been demonstrated for the short-form.

4.15.7.7 Draw-a-person

The use of human figure drawings as a projective method of personality assessment is based on the expectation that how subjects draw people will reveal aspects of how they perceive themselves and feel about others. Clinical use of drawing techniques originated in work with children, and the first formal drawing test, called the draw-a-man, was developed by Goodenough (1926) and later refined by Harris (1963) and Naglieri (1988) for use as a nonverbal measure of intellectual development. Machover (1948) introduced the notion of using human figure drawings as a projective device that generates nonverbal, symbolic messages concerning subjects' impulses, anxieties, and conflicts, and she proposed numerous possible meanings for structural features of drawings (e.g., where figures are placed on the page) and the manner in which various parts of the body are drawn (e.g., a disproportionaly large head).

Koppitz (1968, 1984) subsequently focused attention specifically on draw-a-person (DAP) assessment of young people and used on Machover's interpretive hypotheses to formulate 30 specific indicators of emotional disturbance involving the quality of drawings (e.g., asymmetry, transparencies), special features (e.g., teeth showing, arms clinging to body), and omission of body parts (e.g., no eyes, no arms). Naglieri and his colleagues (Naglieri, McNeish, & Bardos, 1991; Naglieri & Pfeiffer, 1992) have developed further coding refinements to produce the draw-a-person: screening procedure of emotional disturbance (DAP:SPED). The DAP:SPED is an actuarialy derived and normatively based system comprising 55 objectively scorable items, such as the measured dimensions and placement of figures. It is intended as a screening test for classifying young people aged 6–17 with respect to their likelihood of having adjustment difficulties that call for further evaluation.

4.15.7.7.1 Administration and scoring

The DAP is administered by giving subjects a plain 8.5 × 11 inch piece of paper and asking them to draw a person. When they have finished the drawing, they are given another piece of paper and asked to draw a person of the opposite sex from the one they have just drawn. Subjects are further instructed to draw the figure of a whole person rather than a cartoon or stick figure. In keeping with further suggestions by Machover (1951), subjects are also typically asked and to draw a picture of themselves and to provide some thematic content concerning the figures they have drawn.

As elaborated by Handler (1985), there are three alternative ways of eliciting such thematic content: by asking subjects to associate to their drawings, by asking them to make up a story about the people they have drawn, or by asking them specific questions about their drawings. Machover (1951) provided 31 specific questions to be used for this purpose with children, such as "What is their ambition?," "How happy are they?," "What do they worry about?," and "What are their good points?"

As with story-telling techniques, figure drawing methods are most commonly interpreted in clinical practice by an inspection in which personality characteristics are inferred primarily from subjective impressions of noteworthy or unusual features of the figures drawn. Items included in the Koppitz and DAP:SPED scales may often enter into these impressionistic assessments. However, these scales serve only to identify emotional disturbance without contributing in other ways to personality description, such as by indicating how individuals process information, handle emotion, and manage stress. They have consequently not been widely adopted clinically, and there are no other DAP scoring systems that have attracted much attention in the research literature.

4.15.7.7.2 Psychometric foundations

There is very little psychometric foundation for traditional applications of the DAP, and clinical use of this instrument in assessing young people frequently goes well beyond any empirical justification in empirical data. The influential inspection approach used by Machover is neither standardized nor codified, which precludes any systematic evaluation of its reliability or the accumulation of a normative database. Additionally, although it may be reasonable to expect that unusual emphasis on or omission of some body part will reflect some particular concern about the nature or functions of that body part, most of Machover's specific hypotheses concerning the symbolic significance of figure drawing characteristics lack consistent research support (Kahill, 1984; Roback, 1968; Swensen, 1957, 1968).

The Koppitz system is adequately codified and intended to comprise items that have demonstrably low occurrence in the normal population. However, there is no normative database for the system, its reliability is yet to be demonstrated, and there is some question as to whether it can differentiate between well-adjusted and emotionally disturbed children. In a carefully done study in which Tharinger and Stark (1990) compared groups of mood disordered, anxiety disordered, mood/anxiety disordered, and well-adjusted youngsters aged 9.5–14.75 years, the Koppitz signs showed good interscorer agreement but did not differentiate among the subject groups either in mean total score or in the frequency of any of the 30 individual items.

Such findings warrant concern that the DAP may be a faulty projective technique with questionable propriety for continued clinical use. However, it could be that the DAP is a potentially sound method for which there has not yet been sufficiently sophisticated development and evaluation to document its capacities. The previously mentioned work of Naglieri et al. (1991) on the DAP:SPED appears to speak to this point. The DAP:SPED was standardized on a representative national sample of 2355 children and adolescents aged 6–17 years; its objective scoring procedures have generated inter-rater agreements above 90%; its internal consistency (alpha) reliability estimates are 0.76 among 6–8-year-olds, 0.77 among 9–12-year-olds, and 0.71 among 13–17-year-olds; and its normalized total score has shown substantial capacity to differentiate nonpatient youngsters from those with identified behavioral or emotional problems (McNeish & Naglieri, 1991; Naglieri & Pfeiffer, 1992).

Also noteworthy is the work of Tharinger and Stark (1990), who paired their failure to validate the Koppitz system with an investigation of a proposed new system of their own, the DAP integrative system. The integrative DAP is based on a qualitative holistic scoring approach in which drawings are given an overall adjustment rating on a scale from 1 (absence of psychopathology) to 5 (severe psychopathology). Examiners are instructed to base their impressions on their integrated sense of four characteristics of a drawing, with the pathological end of the scale involving (i) inhumanness of the drawing suggesting feelings of being incomplete, grotesque, or monstrous; (ii) lack of agency as conveyed by a sense of powerlessness; (iii) lack of well-being as reflected in negative facial expressions; and (iv) a hollow, vacant, or stilted sense indicating lack of capacity to interact.

In the same study in which Tharinger and Stark failed to validate the Koppitz system, their integrative system total score significantly discriminated the mood disordered and anxiety/mood disordered subjects from the well-adjusted youngsters and also correlated significantly with the Coopersmith self-esteem inventory, thus attesting the capacity of the DAP to depict a youngster's sense of self. Contemporary literature abounds with sharply divided opinion concerning whether the DAP is a worthless test that should no longer be used (e.g., Gresham, 1993; Motta, Little, & Tobin, 1993) or is instead a potentially valuable clinical tool that has too often been carelessly used or inadequately researched (e.g., Bardos, 1993; Holtzman, 1993). Results to date with the DAP:SPED and the DAP integrative system give some reason to believe that improved methodology may yet establish sound psychometric foundations for carefully specified applications of the DAP.

4.15.7.7.3 Clinical utility

Despite its widespread use in describing subjects' personality characteristics, there is virtually no empirical evidence that traditional DAP interpretation has any clinical utility. Smith and Dumont (1995) asked a group of experienced psychologists and graduate students who had been trained in the use of the DAP to review and comment on a case file. They found that these clinicians routinely utilized specific symbolic representations in the drawings to draw inferences about the client's personality characteristics and diagnostic status—even though research does not support any such isomorphic correspondence of specific drawing characteristics to specific features of personality. Aside from the general ethical issues of using test instruments in unwarranted ways, examiners who are preparing forensic testimony jeopardize their credibility by employing the DAP in this manner.

This does not mean that human figure drawings are without utility in the clinical assessment of children and adolescents. First, by contrast with the practical difficulties of administering the full RATC and TEMAS, the DAP is an easily administered measure that requires no test stimuli and usually takes less than 10 minutes.

Second, as a nonverbal measure the DAP can prove especially useful in the evaluation of frightened, reticent, or otherwise uncommunicative young people, and it is unaffected by language difficulties or bilingualism. As noted by Cummings (1986), moreover, many young children may be more capable of expressing their thoughts and feelings in drawings than in words, and drawing pictures is a more familiar activity to most youngsters than most of the tasks that are set for them in a psychological examination.

Third, unusual characteristics of drawings can suggest avenues for further exploration, even in the absence of definitive conclusions about what these features signify. Examiners need to be circumspect in pursuing such avenues, however, lest they prematurely conclude that they are exploring in correct directions. The pursuit of speculative hypotheses is just as likely to lead into blind alleys as down fruitful paths.

Finally, there is ample indication in the contemporary literature that such approaches as the DAP:SPED and the DAP Integrative System can help to identify the presence and severity of emotional disturbance in general and can accordingly contribute to treatment recommendations, planning, and monitoring. In the future, codifiable and interpretable thematic content in subjects' stories about their drawings, comparable to the data derived from story telling techniques, may further enhance the utility of the DAP.

4.15.7.8 House-tree-person

The House-tree-person (HTP) test was devised by Buck (1948, 1985) as a means of tapping the concerns, interpersonal attitudes, and self-perceptions of young people more fully than is possible with human figure drawings alone. The HTP is intended for use with anyone over the age of three and was regarded by Buck as a nonthreatening instrument that can serve well to minimize a child's anxiety in testing situations and to assess personality functioning in multicultural and bilingual settings. As postulated by Buck and subsequently elaborated by Hammer (1958, 1985), subjects' drawings of these three objects are considered to provide symbolic representations of important aspects of their world.

Specifically, the house, as a dwelling place, is expected to arouse feelings toward the subject's home life and family relationships and, particularly for children, attitudes toward their parents and siblings. The tree is seen as encouraging projection of personal feelings about the self that would be more anxiety-provoking to express in drawing a person, because the latter is more obvious in its representation as a self-portrait. More specifically, the way the trunk of the tree is drawn is considered to portray a subject's feeling of basic power and inner strength; the branches are seen as depicting the subject's ability to derive satisfaction from the environment; and the overall organization of the drawing is taken as a reflection of the individual's feeling of intrapersonal balance. Finally, the drawing of the person is expected to reveal aspects of how subjects view themselves, how they would like to be, and what they think about significant other people in their lives.

4.15.7.8.1 Administration and scoring

Although Buck recommends a four-page booklet with pages measuring 7 × 8.5 inches, most HTP examiners use four sheets of standard 8.5 × 11 in paper on which subjects are asked first to draw "as good a picture of a house as you can," then a tree, and then a person of each sex. Subjects are told they can take us long as they wish and draw any kind of house, tree, or person they like. Completion of the drawings is followed by an interrogation phase in which numerous questions devised by Buck are used to encourage subjects to define, describe, and associate to their drawings (e.g., "About how old is that tree?," "What does that house make you think of?" "Is that person happy?" Buck also recommended a chromatic phase of the HTP in which subjects would do a second rendering of their drawings in crayon rather than pencil, followed by another interrogation. There are no data to indicate the frequency with which examiners conduct Buck's full HTP administration or instead limit the test to the pencil drawings, without either an inquiry or a chromatic phase.

Following the example of Goodenough, Buck originally proposed an elaborate quantitative system for objective coding of structural features of the HTP drawings, such as their size and proportions. As best as can be determined from the literature, however, quantitative coding of the HTP has rarely been employed in clinical practice. Instead, clinicians using this instrument typically rely on a qualitative inspection technique to identify symbolic implications of drawing characteristics for aspects of personality functioning. As in the case of interpreting the DAP in the tradition of Machover, many of the interpretive hypotheses for the HTP suggested by Buck and by Hammer are quite specific. A door that is tiny in relation to the size of the house is interpreted as indicating reluctance to make contact with the environment and an inhibited capacity for social relations, for example, and overemphasis on the roots of the tree where they make contact with the ground is taken as evidence of subjects' concerns about losing their grip on reality.

4.15.7.8.2 Psychometric foundations

The entire psychological literature contains only a handful of articles bearing on the psychometric foundations of the HTP. Most of these are over 25 years old, and none of them provides convincing supportive evidence for the interpretive uses of the instrument recommended by its leading proponents. Buck's (1985) 350-page revised manual contains extensive guidelines and case illustrations to facilitate interpretation, but neither reliability nor validity appears in the index. As intriguing as the rationale for the instrument may be to clinicians, especially those who are psychodynamically oriented, there is at present no empirical basis to warrant inferring personality characteristics from it.

4.15.7.8.3 Clinical utility

Similar to the DAP, the HTP offers the potential advantages in clinical practice of a brief, easily administered, nonverbal, and largely culture-free assessment instrument, along with perhaps being even less anxiety provoking than the DAP. Emerging refinements with the DAP suggest that the HTP as well might prove useful in identifying maladjustment in general, monitoring progress and change in psychotherapy, and even in pointing to possible specific areas of conflict and concern. Moreover, like the DAP inquiry, the HTP interrogation can produce story-telling content that in turn can be codified and suggest topics for further exploration. As matters presently stand, however, any such utility remains an unfulfilled potential, and examiners should be circumspect about including the HTP in their test batteries and basing any firm conclusions on it.

4.15.7.9 Kinetic Family Drawing

Machover (1948) and numerous other clinicians who pioneered in using the DAP to assess young people suggested that useful information might also be obtained by asking individuals to draw members of their family. This suggestion was formalized by Burns and Kaufman (1970, 1972) as the kinetic family drawing (KFD) technique, in which subjects are instructed to draw a picture of everyone in their family, including themselves, doing something. These drawings are then examined for such objective features as omissions of body parts or of members of the family and interpreted according to the actions, styles, and symbols represented in them.

Actions in the Burns and Kaufman approach refer to the ways in which the figures drawn are behaving toward each other, which are thought to provide clues to the intensity and emotional tone of their relationships. Styles concern barriers between family members that prevent them from interacting at all, which may be expressed by drawing some of them at a far distance from the others or encasing them in a circle or a box. Symbols comprise a list of specific items, such as beds, flowers, stoves, cats, and the like, the inclusion of which is considered to reflect various specific unconscious impulses or concerns.

Publication of the KFD was followed by a school adaptation of the technique by Prout and Phillips (1974), known as the kinetic school drawing (KSD), in which children are asked to draw a school picture of themselves, their teacher, and a friend or two in which everyone is doing something. The KSD was intended to provide information about peer relationships and about attitudes and concerns related to school in the same manner as the KFD does for family relationships and feelings about the home.

Knoff and Prout (1985a, 1985b) subsequently recommended combining the KFD and KSD and administering both measures for purposes of analysis and comparison. This combined approach, which they call the kinetic drawing system, is expected to identify adjustment difficulties both at home and in school, to clarify causal or reciprocal relationships between family and school-related issues, and to indicate which people in subjects' lives (e.g., father, sister, teacher) are sources of support of tension. In a further extension of this approach, Burns (1987) has developed a kinetic house-tree-person, in which subjects are instructed to draw on a single page a picture of a house, a tree, and a person in "some kind of action."

4.15.7.9.1 Administration and scoring

Similar to procedures followed in other drawing techniques, administration of the KFD consists of giving subjects an 8.5 × 11 inch piece of plain paper and asking them to draw a picture of everyone in their family, including themselves, doing something. Beginning with an interpretive approach modeled basically after Machover's qualitative system, Burns (1982) developed a long list of actions, style, and symbol characteristics for examiners to consider. As summarized by Knoff and Prout (1985a, 1985b), at least four objective methods for coding characteristics of kinetic drawings have also been proposed by various investigators, but none of these has become consistently visible in the literature. A review of the KFD literature by Handler and Habenicht (1994) indicates in general that cumulative knowledge concerning the adequacy and utility of this instrument has been limited by considerable variation in whether and how it has been scored in research studies and applied in clinical practice.

Also of note is a thematic elaboration of the KFD proposed by McConaughy and Achenbach (1994) and called the semistructured interview protocol. In this approach subjects are given the following question to answer after they have completed their family drawing: (i) what are they doing, (ii) what kind of person is [each member], (iii) what are three words that describe [each member], (iv) how does [each member] feel in this picture, (v) what is [each member] thinking, (vi) who do you get along with best, (vii) who do you get along with least, and (viii) what is going to happen next in your picture?

4.15.7.9.2 Psychometric foundations

Handler and Habenicht (1994) were able to reference a substantial number of publications concerning the KFD. However, they were forced to conclude that, despite its widespread use, this projective method has not yet been adequately developed with respect to its psychometric properties. Most of the systems previously proposed for coding KFD characteristics can achieve substantial inter-rater reliability, with percentages of agreement generally ranging well above 0.85 in various studies (Cummings, 1986; Handler & Habenicht, 1994). However, none of these scoring systems has demonstrated satisfactory retest reliability, even after very brief intervals, and there is little empirical basis for challenging the opinion that "the KFD still remains primarily a clinical instrument with inadequate norms and questionable validity" (Handler & Habenicht, 1994, p. 441).

With this in mind, Handler and Habenicht have recommended a holistic, integrative approach to KFD interpretation, much in the manner of the previously noted integrative DAP method used by Tharinger and Stark (1990), rather than the coding and summation of lists of signs and symbols. In the same study in which Tharinger and Stark demonstrated the superiority of their integrative DAP to the Koppitz scoring system, they also found that a holistic method of evaluating kinetic drawings discriminated adjusted from maladjusted children more effectively than a traditional scoring guide for KFD interpretation developed by Reynolds (1978).

In developing his scoring guide, Reynolds urged clinicians and researchers to avoid cookbook approaches that fail to go beyond positing direct and absolute links between individual drawing characteristics and specific personality features. Instead, scores for drawing characteristics should be only a first step in interpreting drawings as gestalts that take on meaning only in relation to a youngster's personal, family, and cultural context. It can be hoped that eventual attention to this sound advice, perhaps through the standardization of integrated coding systems, will establish for kinetic drawings the validity that is presently lacking for them to be used with confidence in clinical evaluations.

4.15.7.9.3 Clinical utility

Conceived as a means of understanding how children and adolescents conceptualize their family and perceive themselves within the family context, the KFD is a potentially useful instrument for elaborating the interpersonal dynamics of young people and orchestrating individual or family therapy for those with adjustment difficulties. By employing the kinetic drawing system, examiners can explore school-based as well as family-related issues for such purposes. Of further potential benefit, subjects from a variety of ethnic and minority group backgrounds have been found to express dimensions of their family culture in their KFDs (Handler & Habenicht, 1994), which suggests a role for this instrument in multicultural assessment.

Unfortunately, however, the previously noted psychometric limitations of the KFD makes its clinical use problematic at present, particularly with respect to basing any firm conclusions on what and how subjects draw. Until such time as adequate research has clarified what the KFD and other projective drawings methods can and cannot do, clinicians are well advised to regard their figure drawing findings as suggesting but not confirming any notions about the subject. We would endorse in this regard the conclusion of Knoff (1990) that "The hypothesis generating use of projective drawings and their ability to be interpreted within various psychological orientations remains both viable and defensible [but] the validity of hypotheses tied to specific drawing characteristics must still be determined" (p. 99).

4.15.7.10 Sentence Completion Methods

Sentence completion methods consist of initial words or phrases, called stems, that subjects are asked to extend either orally or in writing into complete sentences. Typically used stems vary in length and structure from just one or two words, such as "People ..." or "I wish ...," to detailed specification of people or situations, such as "If only my mother would ..." or "When he found he had failed the examination, he ..." As in the case of responses on other projective methods, the manner in which subjects complete sentences is expected to provide an indirect source of information concerning their underlying feelings, attitudes, and level of adjustment. In addition to eliciting general information in these respects, the specificity in many sentence completion stems encourages subjects to reveal their orientation toward particular events and circumstances in their lives.

Sentence completion methods originated in word association tests dating back to the 1890s, and, as reviewed by Haak (1990) and Lah (1989b), were developed during the 1940s and 1950s into a large number of formal and informal versions, of which the most noteworthy published scales were the Rohde, the Sacks, the Forer, and the Miale-Holsopple sentence completion tests and the Rotter incomplete sentences blank (RISB). Of these, the RISB has become the best known and most widely used and includes an adult, a college, and a high school form (Rotter, Lah, & Rafferty, 1992). Also available are more recently developed sentence completion forms constructed by Brown and Unger (1992) for use with adolescents and adults and by Hart (1986) for evaluating school age children. Further comments focus primarily on the RISB, as the predominant and most recently revised exemplar of the sentence completion method, and on the Hart sentence completion test (HSCT), because of its specificity for assessing young people.

4.15.7.10.1 Administration and scoring

The RISB is a 40-item test printed on the front and back of a one-page form and comprised mainly of brief stems (eight have just a single word, 21 have two words, six have three words, and the remaining five have four words). Subjects are given a pencil and asked to "complete these sentences to express your real feelings." The test can be administered either individually or in a group setting; however, Rotter et al. (1992) caution against taking oral rather than written responses, primarily because doing so injects an interpersonal component into the testing administration that can influence subjects' responses in various confounding ways.

The RISB and other sentence completion tests are typically interpreted in clinical practice by the inspection methods we have described previously; that is, examiners read the content of the items and from impressions of what they signify concerning a subject's probable personality characteristics. Rotter et al. (1992) also provide a scoring system for rating each item on a seven-point scale from 0 (most positive adjustment) to 6 (most indication of conflict). These ratings are totaled to yield an overall adjustment score. There is little indication that this or any other codification has received much attention in clinical practice or research studies, even though some work with college students indicated that the overall RISB score can discriminate those who are receiving counseling or psychotherapy from their nonpatient peers (Lah, 1989a).

The HSCT is also a 40-item measure in which the item stems were designed specifically to use with children and to sample family, social, school, and self dimensions of their lives (Hart, Kehle, & Davies, 1983). HSCT scoring involves rating each item as negative, neutral, or positive with respect to adjustment and also rating 10 scales composed of various clusters of items concerned with perceptions of self, family, and school on a five-point negative-to-positive continuum. Criteria are provided for each item to guide examiners in their ratings and thereby to enhance scoring objectivity and the prospects for achieving inter-rater agreement.

4.15.7.10.2 Psychometric foundations

Although there is a substantial RISB research literature, most of the published studies have used the instrument as a measure of adjustment but, as pointed out by Lah (1989a), they were not designed to evaluate its properties. Particularly with respect to its validity, there has been virtually no accumulation of empirical evidence to support any diagnostic or predictive inferences about personality functioning beyond the modestly demonstrated capacity of the RISB to identify maladjustment. Likewise, little systematic progress has been made in assessing the reliability of RISB data and establishing normative standards for them.

This is a regrettable state of affairs because, aside from being a psychodynamically compelling method of enriching personality assessment, the RISB is an eminently codeable instrument for which excellent interscorer agreement has been demonstrated using the Rotter et al. approach (Lah, 1989a). Moreover, as discussed in the introductory portions of this chapter, sentence completion responses have numerous objective, structural, and behavioral components (e.g., time to completion, length of sentences, frequency of self- vs. other-reference, items omitted) that have rarely been considered in codifying these methods or attempting to establish a psychometric foundation for them.

The HSCT coding system has also achieved substantial inter-rater agreement and some preliminary success differentiating between emotionally disturbed and well-adjusted children. However, Hart (1986, p. 269) observed that it remained to further research to demonstrate adequate reliability and criterion validity for his instrument and to develop sufficiently broad normative data. The available literature, circa 1996, suggests that not much if any, progress has been made in this regard.

4.15.7.10.3 Clinical utility

Sentence completion methods bring to the personality assessment battery an easily administered projective test that can be given to groups as well as individuals and requires only about 30 minutes on average for subjects to complete. The scorable 40-item RISB high school form is suitable for high school and most middle school youngsters, and the 40-item HSCT can be used comfortably with younger children. Barring a language or reading difficulty, the meaning of the sentence completion stems is clear, and subjects are not asked to explain, elaborate, or otherwise account for their responses. Hence, incomplete sentence methods are often less threatening or anxiety-provoking than inkblot, story-telling, and figure drawing procedures. However, the previously noted relative lack of ambiguity in sentence completion stems means that subjects are more aware than on other projective methods of how they are presenting themselves through their responses.

At this point in time, the RISB and HSCT can be used with justification to form general impressions of a young person's level of adjustment and to formulate hypotheses concerning possible conflicts or concerns the young person has and how he or she may feel about self, other people, and certain situations. Such hypotheses can justifiably be expressed only as speculations, however, not as conclusions, and they should be considered reasonably correct only to the extent that they are supported by other reliable sources of information.

Haak (1990) has asserted that sentence completion methods can be used effectively with children to rule out intellectual difficulties, attention deficit disorder, and stress and to rule in depression, anxiety, thought disturbance, and defensiveness, and provides detailed clinical guidelines for doing so. These suggestions seem sensible in each case, but they are entirely unverified by empirical data. Hence, like other impressions formed by experienced clinicians, Haak's diagnostic guidelines provide an agenda for confirmatory research, but they should not be elevated from speculations to the status of conclusions until that empirical confirmation becomes available.

4.15.8 FUTURE DIRECTIONS

Projective methods have been extensively used, taught, and studied for many years, and it seems likely that they will continue in the future to be regularly included in test batteries for assessing personality functioning in young people. Survey data cited in this chapter document that over the last 30 years psychologists have continued with much the same frequency to apply these instruments in practice and utilize them in research. During this same period the psychometric adequacy and clinical contributions of projective methods have been regularly and vigorously challenged, and this chapter indicates that the uses to which some of these instruments are put often go beyond available justification in empirical data.

How do we account for the persistent use by clinicians of many such as yet unvalidated methods? One could say that there just happen to be legions of uninformed or unethical clinicians in practice who do not hesitate to employ useless methods if doing so serves their purpose in some way. However, it seems doubtful that a vast segment of the profession deserves to be tarred with such a broad brush of evil. Rather, at least the majority of professionals who use projective methods must have good reason on the basis of their clinical and individual case experience to believe sincerely that these methods provide valid and useful information about personality functioning in ways that have not yet been translated into supporting research data. One could then say that such clinical confidence in projective methods is based solely on illusory correlation. However, it seems doubtful that a vast segment of professional personality assessors could be so thoroughly deluded.

These observations suggest that projective techniques have been and will continue to be used because they yield valuable information and generate fruitful hypotheses in clinical assessments. Hopefully, adequate research methods will lead the way toward improved standardization and codification of projective methods, that will in turn enhance the psychometric foundations on which they rest. As Kuehnle (1996) has pointed out, inappropriate use of projective instruments for purposes for which they have not been validated, such as identifying children as having been traumatized or sexually abused, violates ethical standards and risks causing harm to young people and their families.

More than any of the other projective methods, the Rorschach has had the benefit of rigorous attention to research methodology, as demonstrated in publications by Exner (1995) and Weiner (1995a) and, as indicated earlier in this chapter, this method presently rests on a solid psychometric foundation. What the future of projective methods needs is similar methodological attention to documenting the reliability of other techniques and their validation for various purposes. To say that sophisticated research methods are not applicable to projective methods is as unwarranted as asserting that these methods are by nature invalid. To say that projective test responses cannot be examined scientifically without detracting from their idiographic richness sells projective methods short and prevents them from realizing their full potential.

Along with these needs for improved research and a narrowed gap between data and practice, the most important future direction for projective testing of young people lies in developing adequately representative normative data that will facilitate age-specific and multicultural assessment. There is no lack of projective techniques, but there is a decided lack of reliable information concerning how children and adolescents of different ages, from diverse backgrounds, and with various kinds of personality strengths and weaknesses, should be expected to respond to them. In addition to the nearly empty coffers of cross-sectional normative data of these kinds, the cupboard is virtually bare with respect to longitudinal ata indicating how young people are likely to change over time and with maturation in how they respond to projective tests. Collecting and disseminating such data is the number one agenda item for the future development of projective assessment of children and adults.

4.15.9 SUMMARY

Projective tests are methods of personality assessment in which some degree of ambiguity in the test stimuli or instructions creates opportunities for subjects to structure their responses in terms of their individual personality characteristics, and thereby provide information about the nature of these characteristics. Although projective methods are accordingly more ambiguous and less structured than so-called objective methods, the differences between these methods are relative rather than absolute. All projective tests contain objective as well as subjective features and elicit responses that are representative as well as symbolic of behavior, and they differ from each other in the extent to which they are ambiguous.

Because of their relatively unstructured nature, projective tests measure personality functioning in subtle and indirect ways and tap underlying psychological characteristics at a less conscious level than relatively structured measures. Projective test data consequently provide valuable information about how people are likely to think, feel, and act that is difficult to obtain from objective assessment procedures, and they are also less susceptible than objective test data to the influence of test-taking attitudes.

Projective methods can be used to good effect with children and adolescents as well as adults. The basic interpretive conclusions and hypothesis that attach to projective test variables apply regardless of the age of the subject, provided that examiners determine the implications of their data in the light of normative developmental expectations. Surveys of clinical and school settings indicate that the projective instruments most frequently administered in evaluating young people are the Rorschach inkblot method, the thematic apperception test (TAT), the children's apperception test, the Roberts apperception test for children (RATC), the tell-me-a-story (TEMAS) test, the draw-a-person, the house-tree-person, the kinetic family drawing, and alternate forms of the sentence completion test.

For each of these nine projective tests, this chapter reviews their composition, administration, scoring, psychometric foundations, and clinical utility. Despite widespread utilization of these nine tests in clinical practice to draw conclusions about the personality characteristics, level of adjustment, and treatment needs of young people, only the Rorschach presently rests on a solid empirical foundation. Properly collected and interpreted, Rorschach data provide numerous demonstrably reliable and valid indices that facilitate differential diagnosis and treatment planning for children and adolescents with adjustment difficulties.

The RATC and TEMAS have shown through the development of standardized administration and scoring procedures that story-telling methods have the potential to achieve psychometric respectability. However, further research on the RATC and TEMAS is needed with regard to multicultural and adolescent norms, respectively. With regard to the TAT, recently emerging psychometrically sound schemes for coding specific personality characteristics reflected in thematic content, such as SCORS, appear to provide a basis for empirical decision making.

The other measures reviewed have in various ways also shown potential to be codified and refined on the basis of empirical data, and there is reason to be hopeful that advances in research methodology will eventually close a currently regrettable gap between what is known for sure about these projective methods and what is frequently assumed to be true about them in clinical practice. Until this gap is narrowed, and especially until such time as more extensive normative and multicultural data become available, most clinical inferences from projective data should be regarded as hypotheses to be confirmed rather than as facts on which to base conclusions and recommendations.

4.16.1 INTRODUCTION

Clinical assessment practices typically lag behind the conceptualizations psychologists use to understand adaptive and maladaptive patterns in human functioning. We recognize that personality is a functional whole, but cling to assessment procedures that resemble the proverbial blind men and the elephant. Each method of assessment pertains to one dimension or level of personality, yet we expect different sources of data to confirm one another rather than to reveal the different patterns contributing to the larger mosaic. A clarification of the part–whole relationships with regard to personality assessment promotes an understanding of the place of projective techniques in a comprehensive evaluation. The aims of this chapter are: (i) to facilitate the process of integration of projective techniques with self-report approaches to personality assessment; (ii) to reframe projective techniques as performance measures of personality that differ in their demands from other tasks within the battery; (iii) to show that the central tenets of projective techniques embodied in the projective hypothesis are supported by empirical research in various psychology subfields; and (iv) to demonstrate the utility of projective techniques for assessing schema (the internal representation of reality) and problem-solving strategies to meet the reality demands posed by the task.

That projective techniques do not belong to a particular theory of personality was asserted early on (Auld, 1954). Projective methods yield open-ended responses, and their interpretation can accommodate changing paradigms in various subdisciplines, such as the cognitive and neurosciences as well as in the study of emotion and social cognition. It is easy to say that the framework to understand and interpret responses to projective tasks should coincide with key concepts in the various subdisciplines, but the task of continuously updating the conceptual frameworks that are applied to projective methods remains an ongoing challenge.

Responses to projective tests yield information about the internal structure of personality and provide the context for understanding overt behavior and symptomatology. This emphasis on inner structure is currently shared by social, cognitive, and clinical psychology. Newer appreciation is emerging of the wide role of emotions and unconscious processes (e.g., Bargh, 1994; Clore, Schwarz, & Conway, 1994), as well as of meaning structures (e.g., Bruner, 1986) underlying behavioral expression. Projective methods reveal the structure and process of personality that are largely unconscious, and they differ in important ways from checklists or self-report interviews. In addition, the competencies required by projective tasks can be distinguished from those demanded by other measures in the typical assessment battery such as the Wechsler scales.

Therefore, projective techniques can be viewed as performance measures of personality that reveal inner structures or schema as resources needed in daily life. Each projective method sets a task that requires the application of these structures to respond adaptively. All factors contributing to personality development are involved in shaping these inner structures of meaning. Therefore, the interpretation of responses to projective techniques promotes the integration of knowledge from various subdisciplines.

4.16.2 PATTERNS OF USE

Despite criticisms of projective tests, there continues to be broad interest in the Rorschach and the Thematic Apperception Test (TAT;

Butcher & Rouse, 1996). Most clinical psychology doctoral training programs include formal instruction in the Rorschach (Piotrowski & Zalewski, 1993). In addition, the majority of internship sites approved by the American Psychological Association (APA) value knowledge in Rorschach technique (Durand, Blanchard, & Mindell 1988). The Exner Comprehensive System (Exner, 1993; Exner & Weiner, 1995) has become widely accepted because it provides a more reliable and objective basis for interpretation than was previously available. Surveys find the Rorschach, TAT, and various drawing methods among the top 10 most frequently used assessment techniques (Archer, Marnish, Imhof, & Piotrowski, 1991; Piotrowski & Keller, 1989; Piotrowski, Sherry, & Keller, 1985; Watkins, Campbell, & McGregor, 1988; Watkins, Campbell, Nieberding, & Hallmark, 1995). Interest in the Rorschach and TAT is also evident outside of the USA (Weiner, 1994).

The contrast between the negative evaluation of projective methods by researchers and their continued popularity with practitioners (Piotrowski, 1984) begs for a scrutiny of the assumptions and methods applied to judging the utility of these techniques. This state of affairs calls for an analysis not only of psychometric properties but also of the conceptual and methodological underpinnings pertaining to projective testing. Experienced practitioners continue to use these techniques because they find them helpful. For instance, an advantage of the Rorschach is that the validity of its administration is independent of the client's reading level (Archer et al., 1991). Shneidman's (1951) edited volume presented the conclusions of 16 clinicians who blindly interpreted the same TAT protocol using their own preferred method. Despite different approaches and foci, they were remarkably accurate and consistent with each other. Also included in this volume were Klopfer's conclusions based on a blind interpretation of the same individual's Rorschach record which was highly consistent with those based on the TAT protocols. It should be noted that the interpreters all had one thing in common—they were "experts." In light of what we know about how experts perform (e.g., Chi, Glaser, & Farr, 1987), we would not expect to replicate such findings with more recently trained individuals.

In evaluating the evidence of reliability and validity in the clinical use of the TAT, the training and experience of interpreters was a primary consideration (Karon, 1981). Research designs that isolate response variables and subject them to separate statistical analyses do not mirror the interpretation of projective methods in clinical practice. The clinician simultaneously evaluates multiple dimensions of the response in reference to a psychological construct rather than adding individual response variables. More sophisticated validation efforts are needed that focus-on the integrative approach rather than piecemeal summation of isolated response characteristics (e.g., Handler & Habenicht, 1994). Finally, more refined approaches to validation suggest that different facets of psychological constructs are measured by different techniques. For instance, a comprehensive meta-analysis indicated that projective measures of achievement motivation predict long term behavioral trends, whereas self-report measures predict immediate choices (Spangler, 1992). Refinements in conceptualization and approaches to validation are calling into question earlier criticism based on psychometric shortcomings.

4.16.3 BASIC ASSUMPTIONS OF PROJECTIVE TECHNIQUES AND RESEARCH FROM OTHER PSYCHOLOGY SUBFIELDS

The term "projective technique" was coined by Frank (1939) to describe tests using ambiguous stimuli and/or tasks that are less obvious in their intent and are therefore less subject to faking. The aim of any projective technique is to set a task that allows the individual to express characteristic ways of perceiving and organizing experiences. The uniqueness of the individual's style of responding is particularly evident when stimuli are ambiguous and there is no ready response. Under such conditions, there are many possible ways to approach the task or situation, and the person must actively organize the response. A central assumption of all projective methods is that stimuli from the environment are perceived and organized by the individual's specific needs, motives, feelings, perceptual sets, and cognitive structures, and that in large part this process occurs automatically and outside of awareness (Frank, 1948).

These assumptions about projective testing, first elaborated by Frank (1939) in his analysis of the projective hypothesis, are compatible with converging trends across various subfields in psychology pointing to the role of previously organized inner structures or mental sets in the interpretation of stimuli. Since the cognitive revolution of the 1960s, psychology has undergone a significant transformation by moving away from an emphasis on stimulus–response units to describe human perception and action to increasing emphasis on how humans impose meaning and organization on their experiences (Singer & Salovey, 1991). Within cognitive psychology, simple associational models (e.g., paired associate learning) have become less important in describing ongoing information processing than the organized meaning structures, such as schema or scripts that are brought to bear on the interpretation of experiences (Piaget, 1954; Taylor & Crocker, 1981). At the same time, developments in social psychology (Abelson, 1976; Festinger, 1957; Heider, 1958; Kelley, 1967) led to the exploration of organized meaning structures as the fundamental bases of social action (Wyer & Srull, 1994). In the psychodynamic paradigm, the emergence of object relations theory (Blatt & Wild, 1976) implicitly relies on internal structures similar to schema to guide information processing about the self and other. The considerable work in cognitive, social, personality, and clinical psychology bearing on schema theory and supporting the projective hypothesis is briefly highlighted next.

4.16.3.1 Schema Theory and Projective Techniques

Earlier cognitive work within clinical psychology focused on the role of self-statements and inner thoughts. But clinical scientists interested in the role of cognition have increasingly adopted an information-processing approach to clinical phenomena (Ingram, 1986). This approach focuses on the schema that provide rules guiding behavior in social relationships and appear to influence how information about relationships is stored in memory (Fiske, Haslam, & Fiske, 1991). Well-learned, organized knowledge structures (schema or scripts) have considerable impact on memory storage and retrieval. Projective tasks require the superimposition of previously acquired schematic structures to the perception of stimuli and the organization of the response. Acklin (1994) presented a reformulation of the responses to the Rorschach on the basis of schema theory and information processing. Within this framework, emphasis is placed on the nature and adaptiveness of the schema activated by the stimulus properties.

Memory structures such as schema or scripts that store information about situations, persons, and events guide the interpretation of experiences by providing criteria for regulating attention to lend focus to the process of encoding, storage, and retrieval of information in specific domains (Taylor & Crocker, 1981). Event schema refer to the type of script that organizes understanding of a sequence of events in a stereotyped or routine situation such as ordering dinner in a restaurant (Abelson, 1981). Such a "script is a set of expectations about what will happen next in a well understood situation" (Schank, 1990, p. 7). As long as we know what script others are following, we know how to act and to predict the actions of others. Upon entering a restaurant, we are seated, order from the menu, receive our meal, pay, and depart. This process of comparing experience with the internal schema enables us to perceive rapidly unstated information and to anticipate what will happen next. Some individuals may view situations for which they have no scripts (novel) as challenging, whereas others are stymied (e.g., "speechless") in such conditions.

Person schema include information about the self, others, and their interactions. They deal with the individual's rules for predicting, interpreting, responding to, and controlling affectively charged encounters (Tomkins, 1979). For Tomkins (1979, 1987, 1991), emotion is a key organizer of personal scripts. Once the script has been formed, the script organizes and modifies new experiences to fit the preexisting structure. Person schema develop through the individual's synthesis of past experiences according to the individual's style of processing information (Horowitz, 1991). Therefore the construct of person schema brings together models of perception, cognition, memory, affect, action, and feedback. Furthermore, it has the potential to integrate psychodynamic formulations and cognitive perspectives in understanding personality (Horowitz, 1991; Stein & Young, 1992). This process of interpreting new information according to previously acquired sets takes place without conscious awareness and may also lead to systematic distortions in perception, interpretation, and action in interpersonal encounters.

Causal schema give rise to attributions about the causes of events. Schema theory and attribution theory overlap in that attribution theory maintains that individuals are motivated to make causal inferences about experiences and that attributions are made in ways that are congruent with existing schema of self and other, and of the assumed relationships between causes and effects (Tunis, 1991). The relationship between such causal attributions and depression has been studied.

Evidence for the existence of schema is seen in their consequences for information processing, particularly in how information is remembered and retrieved. Schema-driven information processing involves the application of organized knowledge structures akin to theories that govern the perception and interpretation of facts. Thus, schema function to allow general knowledge to influence perception of specific experiences. Schema increase efficiency in identifying perceptions, organizing them into manageable units, filling in missing information, and selecting a strategy for how to obtain further information if needed. Because schema guide behavior in adaptive and maladaptive ways, their study pertains to clinical psychology as well as to the general study of personality, cognition, and social perception. Understanding the recurrence of maladaptive interpersonal patterns is facilitated by studying the operation of schema along with the realistic properties of the current situation (Horowitz, 1991).

The overlap between schema or script theory and the projective hypothesis is evident in their common features. The development of schema or scripts and their retrieval from memory represent an unconscious process through which past perceptions influence the interpretation of current situations. These are precisely the processes that are assessed with projective techniques. The focus of projective methods is on the application of schema to the task demands (e.g., how schema influence the response process) and, by extension, to life challenges requiring similar adaptations.

Even though schema are structures of the mind, they must be sufficiently malleable to adapt to new situations and new configurations of events (Rummelhart, Smolensbus, McClelland, & Hinton, 1986). Therefore, it is appropriate to view schema as emerging when they are needed "from the interaction of large numbers of much simpler elements all working in concert with one another" (p. 20). A distinction has been made between enduring schema and working models (Horowitz, 1991). The former are intrapsychic meaning structures containing generalized formats of knowledge that can be activated by other mental activities related to that knowledge such as motivational concerns (Fiske & Taylor, 1984). Working models combine internal and external sources of information, such as when the individual is actively contemplating an interpersonal situation or task such as the TAT. Working models actively integrate stimuli from a current situation with past knowledge through triggering of an associative network of ideas drawn from enduring person schema.

A person's repertoire may include several different enduring person schema in relation to a given type of relationship, situation, or activity. The working model may incorporate different elements from each of the person schema. The wider the repertoire of enduring person schema, the more flexibility in constructing working models of interpersonal situations. Discrepancies between working models and active, enduring schema may contribute to upsetting emotional experiences. Working models may not match the actual qualities of current social situations, leading to errors in judgment and behavior and to subsequent negative emotions. The aim of many psychotherapeutic techniques is to promote conscious awareness of unconscious, schematic functions. Such awareness may permit the individual to actively override some of the influence of the unconscious information processing.

Scripts or schema may be further organized into metascripts (Singer & Salovey, 1991) that reflect the individual's style of dealing with scripts. These superordinate schema may explain resilience because they influence how individuals reshape their schema when confronted with daily stress, unforeseen failure, or unexpected upheaval. Those with more complex schema may be more willing to replay negative information to explore a variety of alternative schema or scripts. More flexible schema involve the realization that current ideas that seem so clear and self-evident at the moment may change as a function of new experience. This process cannot be taught directly, but is a byproduct of experiencing changes in perception, understanding, and feeling in light of new information. Consequently, it is important to assess the style of synthesizing experience through the organization and reorganization of schema.

Analysis of responses elicited by projective techniques can be informed by models of schema development. Abelson (1976) assumes that schema begin as representations of single concrete examples and become more abstract. Rudimentary schema are compilations of single, concrete examples that are used to make snap judgments about seemingly similar instances. Stereotypic schema encompass the most representative features of events, persons, or groups. More abstract schema recognize inconsistencies between reality and the activated schema. The individual is aware of complexities and ambiguities rather than simply encoding schema–congruent information. Highly developed schema permit the individual to engage in complex information processing seemingly effortlessly and without awareness. The more abstract the schema, the more flexibly they can be applied because they include conditional and inferential concepts, abstract rules, and affective information. The progression from rudimentary to more complex schema is the product of experience and the degree of active, strategic effort brought to the structuring and organization of experience. Schema theory recognizes the role of affect, motivation, and biological factors (genetics, temperament), as well as environmental influences (stress and supports) as they interact with cognitive processes. The shaping of schema, especially social scripts by culture, is also acknowledged and has been studied by anthropologists and linguists (Quinn & Holland, 1987).

Responses to projective methods may be evaluated according to aspects of schema described above. When telling stories to picture stimuli, some individuals superimpose associative elements without an organizational network; others impose stereotypes that may or may not precisely fit the stimulus configurations; still others draw creatively on various elements of their experiences to tell a cohesive story that captures the gist of the stimulus and complies with the instructions. If an individual is presented with a TAT picture that cannot be readily explained by a stereotypic script or an intact schema, then the respondent is called upon to actively construct a script to fit the situation. Similarly, when faced with inkblots that are rough approximations of real objects, the individual must remain flexible in applying schema to answer the question "What might this be." Those who rely on more rudimentary schema will make associations directly from discrete portions of the stimuli. However, those who apply more cohesive schema find a meaningful framework with which to integrate disparate or complex stimuli.

Two aspects of long-term memory structures (schema), procedural and declarative knowledge (Anderson, 1983; Kihlstrom, 1984), are relevant to the interpretation of projective responses. Procedural knowledge refers to unconscious processes or skills such as the structure of language, the organization of music, or other implicit rules that order information or perception. Declarative schematic structures entail the recall of factual information such as names, locations, and historical events. Responses to projective techniques reveal the implicit organization of knowledge as well as the content that enters awareness in response to the stimuli presented. Interpretive approaches can focus on the organization of schema by examining the structural aspects of responses and the sequence of ideas expressed, as well as by analyzing the content.

4.16.3.2 Unconscious Processing of Information

The idea that human behavior is based on a considerable storehouse of organized knowledge structures operating outside of conscious awareness is now widely accepted by cognitive psychologists (Bargh, 1994). Since the 1970s, increasing evidence suggests that information not accessible to conscious awareness influences memory, perception, and thinking (Kihlstrom, 1990). Efforts to refine assumptions about unconscious processes continue across the various subfields of psychology and are not restricted to projective testing or even to clinical psychology.

Social cognitive psychology (social cognition) has become increasingly interested in unconscious thought processes of mental representations of situations, self, and others (schema) and in the interaction of cognition and affect (Wyer & Srull, 1994). Attitudes, expectations, or schema that are strong enough to be automatically activated have been described in terms of their "chronic accessibility" (Fazio, Sanbonmatsu, Powell, & Kardes, 1986). Chronically accessible schema may be cued by emotions arising in ambiguous situations, including reactions to projective stimuli. According to Westen (1993), "Research on chronic schema accessibility has confirmed the projective hypothesis that in ambiguous situations enduring interests, concerns, needs, and ways of experiencing reality are likely to be expressed" (p. 381). Bargh (1994) suggests that temporarily accessible schema due to a recent experience can mimic chronic accessibility and constitute a pitfall for studies of enduring cognitive structures. Indeed, this pitfall is common in the use of personality tests, be they questionnaire or projective devices. The distinction between state and trait variables acknowledges states as temporary conditions of mentality, mood, levels of arousal or drive, and these states may be related to temporarily evoked schema. One of the advantages of projective measures is the opportunity to examine both the structure and content of schema even if temporarily evoked. The content of the schema may be more susceptible to influence by such variations in experience than the structure. However, data are needed to support this contention.

A dramatic demonstration of the effect of a recent experience occurred one semester when the author's students administered assessment batteries to incarcerated youths (generally between the ages of 18 and 22) to determine educational strategies. A great number of TAT stories ended by the characters "talking about it and solving their problem." After some investigation, it was learned that a communication program had been recently instituted to teach the value of resolving conflict by talking things out. A close inspection of the stories themselves revealed that the schema about communication were not well developed but verbalized as a stock ending apart from other components of the problem-solving process. For example, the problems were poorly understood, and characters' feelings, perspectives, and intentions were vaguely or inaccurately deciphered, if at all. The idea for talking about the problem became accessible to conscious awareness through training as declarative knowledge but without the understandings or procedural knowledge needed for its implementation. Conscious awareness of the benefits of communication was not combined with the implicit and largely unconscious understandings and affective reactions that promote such interactions. This example illustrates the importance of studying the inner logic and cohesiveness of schematic structures to discover how story content derived from recent experiences (including vicarious ones such as books or movies) is integrated with other aspects of the task demand such as accurately perceiving the stimuli and following instructions. Both declarative and procedural knowledge must be addressed to overcome the pitfall of attributing too much weight to content that is not meaningfully incorporated into guiding structures.

4.16.3.3 Inert Knowledge vs. Usable Knowledge

Inert knowledge has been described as information that the person knows, but does not apply unless explicitly cued or prompted to do so (Bransford, Franks, Vye, & Sherwood, 1989). The reason why a person fails to use relevant knowledge to solve particular problems is that this information does not spontaneously come to awareness in the context of that problem, or that the schema for applying the information are not sufficiently developed. The manner in which knowledge is encoded and organized in the first place determines its subsequent accessibility and applicability in other situations.

Effective learning in general requires active strategies to organize and recall information such as rehearsal or breaking down the task into manageable units. Torgesen (1977), who introduced the concept of the inactive learner, reported that learning-disabled students exhibit a learning style characterized by minimal planning and limited use of strategies. Individuals may process information from one domain more thoroughly than in others, or the inactive stance may be more pervasive. This inactive style is manifested by processing information exactly as it comes in (memorization) without organizing and restructuring it. In the absence of active, effortful, strategic processing of information, the knowledge may be dormant in memory and not available for use unless externally prompted.

Different types of tasks are needed to differentiate knowledge that is used spontaneously to solve problems from knowledge that is available only when cued by the context. Everyday behavior requires spontaneous use of prior knowledge to make social judgments or other decisions; the possession of factual knowledge is far removed from problem solving in everyday encounters. The TAT stories of the incarcerated youths referred to earlier shows how knowledge may be stated without being embedded in a usable framework. Projective measures differ from typical cognitive tasks and self-report measures of personality in ways that have relevance for distinguishing between inert and useful knowledge. Rather than being asked to provide specific information about the self, the respondent is provided with a relatively unstructured task and asked to give an open-ended response that is evaluated by a professional. Likewise, solving verbally communicated problems such as those on intelligence tests does not resemble the conditions of everyday situations. Such problems tend to contain words that act as cues for accessing relevant knowledge, whereas everyday problem-solving requires the individual to size up relevant features of the situation to notice that there is a problem (Sternberg, 1985). Real problems are accompanied by emotions that shape the way the individual thinks about the problem. Individuals may verbalize several acceptable alternatives for handling a situation, if prompted. Nevertheless, when faced with real-life dilemmas, they may be unable to translate this knowledge into appropriate action. The projective tests reveal the spontaneous accessibility of the schema that guide the application of what comes to awareness.

4.16.3.4 Affective and Motivational Influences on Cognition

Most studies in this area focus on the way mood or emotion influences memory and judgment (Isen, 1984, 1987) and on unconscious processing of information (Uleman & Bargh, 1989). Epstein (1994) describes the impact of emotion on thinking and argues for the existence of two fundamentally different but interactive modes of information processing: a rational system and an experiential system driven by emotion. Thinking in the experiential system is shaped by emotion and tends to occur without deliberate effort or conscious awareness. The rational system is characterized by a more deliberate process of thinking and of acquiring information such as through textbooks and direct teaching. Epstein explains that stories and anecdotes spice up an otherwise dry lecture because they increase emotional engagement and thereby appeal to the experiential system.

Emotions dramatically alter the thought process and influence behavior. Thinking is transformed by intense emotion in the direction of being categorical, personal, concrete, unreflective, and action oriented. The product of such thinking is likely to be considered as self-evident and not requiring proof (Epstein, 1994). Depressed affect is associated with preference for immediate gratification in place of delayed but more substantial rewards (Wertheim & Schwartz, 1983). Anxiety tends to bias the interpretation of ambiguous text (MacLeod & Cohen, 1993). Chronically experienced negative emotions appear to have a cumulative influence on the development of cognitive structures amenable to assessment with projective techniques. Children temperamentally prone to experience negative affect told stories to TAT stimuli that reflected less complex information processing and more reactive self-regulatory styles dominated by more immediate concerns than their less emotional peers (Bassan-Diamond, Teglasi, & Schmitt, 1995).

The following vignette shows how intricately problem solving is tied to emotions (*Readers Digest*, May, 1982, p. 79. Quoted from Jim Whitehead, quoted by Seymour Rosenberg in Spartanburg, SC *Herald*):

> Two hikers were walking through the woods when they suddenly confronted a giant bear. Immediately, one of the men took off his boots, pulled out a pair of track shoes and began putting them on. "What are you doing?" cried his companion. "We can't outrun that bear, even with jogging shoes." "Who cares about the bear?" the first hiker replied. "All I have to worry about is outrunning you."

Now what if the two were husband and wife, parent and child, or very close friends? The emotional investment in the relationship would change the problem to how can "we" escape or even how can "you" reach safety. A parent may suggest that the child run for it. The automatic influence of affect in defining the range of acceptable solutions to problems is evident. Westen (1993) observes that cognitive psychologists do not focus sufficiently on the motivational and emotional factors of unconscious processing of information. Affect and motivation can enhance or disrupt the degree of organization and resourcefulness in the acquisition and subsequent application of knowledge structures.

4.16.3.5 Narrative Psychology and Thematic Apperception Techniques

The analysis of narrative has been a rich source of data in studying the schema or scripts that individuals bring to current understanding of experiences. The social-cognitive approach examines the memory system by analyzing the individual's style of processing and organizing information. Memories such as self-defining experiences (Moffit & Singer, 1994) or incidents of being rejected (Baumeister, Wotman, & Stillwell, 1993) are examined to extract abstract rules and cognitive principles. A study on script formulation (Demorest & Alexander, 1992) first asked participants to generate autobiographical memories. Scripts extracted from these memories were subsequently (one month later) compared with those derived from participants' invented stories in response to affective stimuli. The scripts drawn from fictional stories were similar to those derived from autobiographical memories. These findings suggest that scripted knowledge structures are superimposed on new affective stimuli.

Schank (1990) addressed the question of how stories exchanged during the course of social conversation are accessed in memory. To understand how a person is reminded of a story to tell at the right moment in a conversation requires breaking it down into themes, plans, goals, actions, and outcomes (Schank, 1990). These elements constitute a filing system for indexing the relevant components of experiences to be stored in memory and subsequently retrieved. A higher level organization of these concepts involves a prediction, a moral, or a lesson learned. When a lesson repeatedly occurs, it becomes a type of structure that exists apart from the specific stories from which the lesson arose.

For Schank, telling a good story at the right time is a hallmark of intelligence because it represents an understanding of what is being talked about now through its connection with the lessons that the listener has stored in memory. Recalling an appropriate story to tell and understanding how it relates to what is currently being spoken about depends on how the stories are catalogued in memory. It seems logical that individuals who engage in more active and reflective classification of experience for storage into memory are also more likely to be reminded of an appropriate story at the right moment in a conversation. This framework is directly applicable to the interpretation of stories told to TAT-like stimuli. Respondents are reminded of a story by the stimulus, but the particular story details are shaped by convictions or lessons learned from experience.

One way to validate constructs is through the congruence of models drawn from various lines of research. Arnold (1962) proposed that individuals express their basic attitudes or convictions in their TAT stories, and that these convictions constitute their motivational set. Like Schank, she focused on goals, plans, actions, and outcomes as the basic ingredients of the story import or lesson learned.

The rise of narrative psychology has the potential to enrich story-telling methods of personality assessment. Analysis of narratives such as those elicited by the TAT is considered useful for clarifying the degree of complexity and organization of information processing pertaining to the synthesis of experience (Carlson & Carlson, 1984). These cognitive and perceptual processes can also be assessed through the Rorschach technique. It has been suggested that the Rorschach should combine its emphasis on perception with a focus on cognitive representation (Blatt, 1992).

4.16.4 LEVELS OF PERSONALITY ASSESSED BY PROJECTIVE AND QUESTIONNAIRE METHODS

Projective methods measure different dimensions or levels of personality than self-reports. One of the clearest ways to understand the unique contribution of projective techniques is in the context of understanding these levels. McAdams (1995) proposed three conceptually distinct levels of understanding personality: level one—traits or stylistic, habitual tendencies; level two—developmental or motivational constructs such as goals, plans, and strivings; and level three—the life narrative or the evolving story that is internalized to provide broader meaning, purpose, and cohesiveness to specific experiences. McAdams does not describe relationships among the levels, though it seems logical to assume that they are not independent since they are different perspectives (or units) on the functional whole. For Klopfer (1981), a trait itself can be understood at three levels. First, as viewed by significant others or the public image (with or without awareness); second, as viewed by the individual or conscious self-concept; and third as manifested (with or without awareness) in behaviors such as responses to projective tests. This emphasis on the source of the data is consistent with a fundamental distinction between two levels of personality, based on the perspectives of the actor and observer (Hogan, 1987). Projective tests were better able to predict peer rankings on four personality traits (publicly observed image) than the individual's self-report of those traits (McGreevy, 1962). Different techniques may be useful for elucidating different levels or dimensions of personality. However, a comprehensive understanding requires a framework for how the different levels relate to one another.

Measuring achievement motives through self-report of intentions, goals and reasons for actions (self-attributed) and inferences drawn from stories written to picture stimuli (implicit) are not equivalent (Koestner, Weinberger, & McClelland, 1991; McClelland, Koestner, & Weinberger, 1989). McClelland and colleagues propose that the general absence of significant correlations between measures of self-attributed motives derived through self-report, and implicit motives inferred from stories, cannot be ascribed to the worthlessness of projective measures nor to poorly designed questionnaires, but must be taken seriously as evidence that these are in fact different variables with the same name. Rather than seeking to remedy deficits in either type of measure, they suggest that it may be more fruitful to acknowledge them as reflecting two qualitatively different kinds of human motivation. They contend that implicit motives develop by intrinsic enjoyment generated when doing tasks or experiencing activities, and predict spontaneous goal-directed actions sustained over time even in the absence of specific social demands. However, self-attributed motives are built around explicit social incentives or demands of socializing others, and predict responses to situations structured to provide such incentives. The implicit achievement motivation does not give information about the area of life to which a person will direct efforts to succeed. Self-attributed motives, plans, and goals may express the person's conscious intentions but do not give information about the person's commitment and capacity to follow through. Under specific conditions, self-attributed motives act like implicit motives in that they energize, direct, and select behavior. However, the problem with predicting long-term behaviors from self-attributed motives is that the social incentives may not be salient enough to elicit the behavior. Implicit motives exert relatively greater influence because they drive activity that is inherently enjoyable even in the absence of specific social demands.

The acquisition of implicit and self-attributed motives such as proposed by McClelland and colleagues may relate, respectively, to the experiential and rational systems discussed earlier (Epstein, 1994). Learning in the experiential system takes place in an affective context where emotions and interests drive attention and information processing. Additionally, the development of these two types of motives may involve different principles of learning (Meissner, 1974, 1981; Raynor & McFarlin, 1986; Sandler & Rosenblatt, 1962). One pertains to the acquisition of cognitive skills that are functional and enlarge the individual's repertoire of adaptive capacities through the teaching and reinforcement of these competencies. The other relates to the development of the inner world or the self-system that provides relative independence from external incentives. The advantage of developing this inner structure is to shift from dependence on external supports to increased reliance on self-regulatory mechanisms (Meisner, 1981). These regulatory functions increase the individual's capacity to master the environment, endure stress, and delay gratification of impulses.

The development of increasingly complex and differentiated self-regulatory structures or schema takes place at a level of organization that is different from that of acquiring behavioral patterns through reinforcement. Such development relies on the individual's integration of life experience to seek consistency within the self (Raynor & McFarlin, 1986). However, emotional, cognitive, and attentional limitations interfere with synthesis of life experiences and detract from the development of inner self-regulatory structures. For example, the domination of awareness by that which is immediately striking or concrete is not compatible with the development of long range interests, values, or aims. The primary affective impediment to the internalization of such self-regulatory values are the limitations in the capacity to sustain emotional involvement in interests that are relatively remote from personal needs (Shapiro, 1965).

Motivation can be understood in relation to two necessary ingredients: the goal or intention and the self-regulatory capacity to sustain goal directed action (Arnold, 1962; Kuhl & Beckmann, 1994). Thus, a stated goal or intention such as playing violin in a symphony orchestra may be difficult to implement and sustain, regardless of musical talent because of the rigorous independent practice required. Such sustained effort is facilitated by the enjoyment of and interest in the activity. Otherwise, careful programming of external incentives is needed.

Understanding the gaps between a person's stated goals or intentions and the individual's self-regulative resources is crucial to planning interventions. A 19-year-old college student was referred by her therapist for an evaluation because no meaningful discussions were taking place after six months of regular attendance of sessions. Sandra was in therapy at the insistence of her family because "she had no direction in life." During the initial interview with Sandra, she described her erratic schedule of eating and sleeping, her general lethargy and boredom, as well as sporadic class attendance. She reported having similar problems in high school such as difficulty getting up, missing school once a week, not studying, and cheating to get by. She stated emphatically that she was not depressed.

When asked directly about drug use, Sandra reported significant involvement starting in the fifth grade. She did not discuss this issue with her previous therapist because "no one asked me." She described the therapist as not providing enough structure during the sessions so she just talked about meaningless topics. Sandra verbalized her desire to achieve and recognized that she was not accomplishing her goals. At the same time, she admitted that she found school work aversive.

As part of the evaluation, the TAT, the Wechster Adult Intelligence Scale (WAIS-R), and Rorschach were administered among other measures. The first five TAT stories that she told are given below to illustrate the lack of connection between Sandra's goal setting and means toward their attainment. The emphasis is not on developing a comprehensive clinical picture but on presenting general conclusions about each story that are pertinent to Sandra's motivational schema:

> *Card 1.* Don't like pictures. Not all of them . . . Umm . . . like story—like once upon a time. This is a boy . . . He's . . . OK, he . . . is it a violin? I don't know. Can I say two things? (Whatever you want). He's either frustrated because he can't play it or he's sad because he's not allowed to play it anymore. He wants to play it but for some reason he can't . . . (stares at picture) (TO) He becomes a great (did I say that was a violin?) violin player, and he's happy. (OK, I think you have the idea.)

Sandra is immediately put off by the task and vacillates in her interpretation of the picture as she does in her own intentions. The story content is appropriate to the stimulus, but Sandra cannot determine whether the boy is experiencing internal (frustration) or external (not allowed) barriers to achievement. In any case, the boy takes no heed of these problems and becomes a great violin player, seemingly without effort. This unrealistic connection among circumstances, intentions, actions, and outcomes suggests that Sandra's schema do not include a clear grasp of the obstacles to achievement nor of the steps needed to attain goals.

> *Card 2.* God! These things are … OK, there's … (stares) … This girl on her way to school, she's walking to school, and she sees this man working in the field, and that's his wife watching him. His wife's talking to him I guess, may be talking to him. He's working with his horse on the farm, and she's thinking that she doesn't want to look like that when she gets older (like the lady). She doesn't want to live on the farm. She feels sorry for that lady, for both, for the lady. So she goes to school to get an education so she's not like them.

The girl goes to school not because she really wants to learn but to avoid becoming what she fears. Sandra's schema about the importance of education does not include a positive affective quality nor the spontaneous accessibility of the effort involved. Sandra does not delve into the purposes and inner life of the characters but relies on the stimulus, on external appearances (doesn't want to look like the lady), and social convention (getting an education). Thus external structures and supports are important in guiding her reactions.

> *Card 3BM.* Don't know what this is … umm … guess it's a girl. A boy or girl, either sleeping, crying, or … umm … (frustrated) don't even know what. (repeat directions) I guess she's crying because … OK, this doesn't make sense though. (stares as if answer is in the card) I think they're car keys. No idea. This is dumb. She's crying because … what is that thing is … someone stole her car. She has no way home from this place. So then she calls the police and tells them that her car is missing. Eventually they find her car, and then she's happy. Can you tell me what that is? (It can look like different things to different people.)

Sandra initially vacillates before settling on a plot. She became frustrated, stated that the task was dumb, but responded to encouragement. This tendency to blame outside factors is consistent with her reliance on the environment to regulate her behavior. The outcome of getting the car back only deals with part of the problem. Having "no way home from this place" was not addressed. Sandra's incomplete processing of information (only dealing with part of the problem, leaving out details called for in the directions) and limited resources (no internal representation of possible support; indecision and disjointed approach to narrating the story) suggest why she cannot regulate her behavior.

> *Card 4.* OK, … this is a man and a woman who … they either just had a fight, or he wants to go somewhere, and she doesn't want him to go. OK, she's trying to persuade him either not to go or to forgive her. And then, I guess eventually he does it, he forgives her or he doesn't—or he might go, or he'll stay. And they live happily ever after.

Again, Sandra cannot commit to one story line, and the characters' intentions or reasons for acting are not examined. As with the previous stories, she seems unable to develop her ideas clearly beyond the initial identification of the tension depicted in the card, suggesting dependence on external stimuli. Her vacillation about what's going on in the picture (noted in several picture cards) suggests that she feels uncertain about her judgment in situations that are somewhat ambiguous. As in previous stories, the ending is unrealistically positive as Sandra does not make appropriate connections among intentions, actions, and outcomes.

> *Card 5.* OK, can you make up people who aren't there? This is a lady who is coming to tell her children it's time for their nap. So she sticks her head in and says it's dinner time, and all the kids come to dinner. Everybody eats dinner, and kids go back and play. In the library, den—I think it's supposed to be the library.

Sandra's query about introducing additional characters further points to her need for external guidance. The lady intends to tell the children that it's time to take their nap but ends up calling them to dinner. This twist in the story suggests that Sandra is not monitoring story details (also seen in other stories) and that she has similar difficulty keeping track of her own intentions.

Generally, Sandra is able to recognize the conflict or tension in the pictures but has difficulty sticking to one explanation. Sometimes, she does not monitor story details sufficiently, leaving gaps or contradictory details. She does not examine feelings, thoughts, or intentions and has difficulty connecting planful, realistic actions with outcomes. She cannot develop the themes that she introduces beyond a vague and Polyanna-like story. Sandra persists in staying in school because she believes that the way to ensure her future is to get an education but is not able to get invested in the process of learning. Sandra is floundering in the unstructured campus setting because she has not developed the inner structures (implicit motives) to regulate her attention and behavior.

When she received the results of the evaluation, Sandra easily identified with the example of someone who thinks an exercise program is needed and joins an aerobics class but does not attend for one reason or another (too tired, too cold). She agreed that even the thought of doing school work is aversive, and the key was in finding ways to side-step the aversive elements, possibly through social supports. She acknowledged that by joining a sorority, she would have peers to eat with on a regular basis, and the structure would help her keep a schedule and attend class. At first, she worked on seeking the external incentives that would motivate her behavior and through these initiatives began to feel she had some choices and control over her life. Subsequently, therapy sessions focused on ways to build these structures and prompts into her daily routines to gain increasing independence.

Sandra's schema as assessed with the TAT did not include connections among goals, plans, actions, and outcomes, and these resources were not available to guide her daily behavior. The therapeutic aim was to help Sandra deal with the factors that impeded the development of these connections. She could not have verbalized these impediments in an interview or self-report measure because she was not aware of them. Likewise, the more structured Wechsler scales did not reveal the sources of her difficulty. Therefore, sole reliance on such measures would have been insufficient.

4.16.5 SELF-REPORT VS. PROJECTIVE PERSONALITY TESTING

The foregoing discussion has already demonstrated that self-reports, even if candid and accurate, may predict behavior only when social incentives are operating or when the situation is structured to prompt the response. However, it is useful to contrast questionnaire and projective devices as direct and indirect methods of personality assessment (Vane & Guarnacia, 1989). Direct methods are comprised of observations of behavior, inventories, or interviews. The indirect method utilizes relatively unstructured stimuli such as the TAT, Rorschach, or drawings. In the latter, the information sought is not readily apparent and, therefore, difficult to manipulate. Vane and Guarnacia cite the following problems with the direct method: (i) limitations of self-knowledge preclude accurate self reports; (ii) test items are open to misinterpretation; (iii) real-life situations cannot be represented by pencil and paper items; (iv) desire of the respondent to manage impressions need to be overcome by including scales to detect faking or response sets; (v) inventories yield information without clues for understanding the reason; and (vi) the relationship between traits on inventories and behaviors is complex

Multiple choice or other highly constrained response formats do not give clues about the style of organizing the response. The respondent is asked to tell versus show. Thus, no evidence exists beyond self-report to judge response parameters despite availability of norms. Finally, responses to structured questions only tap conscious phenomena. Therefore, methods such as interviews or self-report inventories provide what the individual is capable of perceiving and is willing to share. However, responses to projective testing can be evaluated by analysis of various parameters.

Both direct and indirect sources of information are useful depending on the purpose. Self-reports are susceptible to conscious or unconscious distortion and reveal only one dimension of the personality. Nevertheless, it is important to obtain information that the respondent willingly discloses. Self-reports are easily scored and amenable to traditional methods for estimating reliability and validity. Projective methods require extensive training, are time consuming, and require more cumbersome methods to establish psychometric credibility. However, their purpose is not evident to the respondent, and they provide information that is different from other sources of data. The use of both direct and indirect methods is likely to yield the most accurate picture.

4.16.6 CONTRIBUTION OF PROJECTIVE TECHNIQUES TO DIAGNOSIS AND INTERVENTION

The process of responding to the projective task can be conceptualized as an attempt to impose meaning on the stimuli presented and to comply with the instructions given. Analysis of the response reveals the individual's schema or scripts, both in terms of the structural organization of experience and the content of awareness. Appreciation that the manner in which individuals acquire, organize, and represent knowledge into cognitive schema have a fundamental influence on the way they behave, guides the use of projective techniques. Rather than looking for one-to-one correspondence between test responses and inferences, such as searching for aggressive content in projective tests, it is more fruitful to explore processes that promote aggression in particular situations. The social-information-processing model of children's social behavior (Crick &

Dodge, 1994) details the social-information-processing steps that precede aggressive behavior in specific situations. According to this model, aggressive behavior can be understood in terms of how individuals encode social cues, how they interpret those cues, how they select and clarify goals, how they generate possible solutions to perceived problems or dilemmas, how they make decisions about the selection of responses, and how they execute and monitor the selected behavior. Information regarding each of these steps in social information processing can be gleaned from responses to projective techniques.

Thematic apperceptive methods can provide information about the attribution of intentions for others' reactions, the interpretation of social cues, the anticipated consequences of alternative actions, as well as about the cognitive flexibility and organization of the individual's meaning structures. Information about the execution of the behaviors is provided at two levels: how the characters follow through on intentions and resolve problems, and how the narrator develops and monitors the story. Any aggressive content that is expressed can then be better understood in light of the aforementioned processes.

Responses to the Rorschach also clarify social information processing that promotes aggression. For example, a preponderance of answers that simplifies the stimulus (e.g., high lambda) suggests that the individual may be involved in confrontational situations because of a tendency to make decisions without considering important cues (Exner, 1993). The connection between such responses to projective tasks and aggressive behavior is borne out by research suggesting that aggressive children selectively attend to and recall aggressive cues, partly because they respond prior to processing all of the available information (Dodge & Feldman, 1990).

A taxonomy of psychopathology comprised of a descriptive, atheoretical compilation of symptom categories (e.g., *Diagnostic and statistical manual of mental disorders*, 4th ed. [*DSM-IV*]) could be enhanced by a framework that relates these symptoms to basic structures of psychological organization. Within a diagnostic category such as autism, there exists a wide variability of impairment in functional capacities. Responses to projective techniques can range on a continuum from being flexibly adaptive to demonstrating various levels of impairment that can go beyond a specific diagnosis. The manner in which an individual uses the cues in the stimuli and responds in an organized way to the task demands is an index of the differentiation and organization of previously developed schema. Furthermore, responses reveal whether the person must be prompted to respond or actively restructures knowledge for adaptive use in stressful or ambiguous situations.

Horowitz (1991) envisions a future *DSM* Axis II as incorporating three interconnected components: (i) recurrent maladaptive patterns of self-regard and interpersonal behavior; (ii) person schematic characteristics explaining that behavior—this would include the developmental level of self-organization; and (iii) style of self-regulation comprised of habitual control processes leading to coping and/or defense. An example would be how a person regulates emotionality by inhibiting or facilitating the activation of schema. Horowitz's conceptualization implicitly recognizes that any Axis I diagnosis, such as attention-deficit hyperactivity disorder relates to the development of inner schema. Difficulty regulating the attentional process may interfere with the active and strategic synthesis of knowledge gained through experience. Without organized schematic structures, the individual may not be able to govern behavior according to internalized rules and standards, a prominent characteristic of individuals with attentional deficits (Barkley, 1990). Responses to open-ended projective tasks represent the convergence of all of the individual's traits on the organization of experience, including compensatory strategies that could mitigate against risk factors.

A changing emphasis within psychoanalytic theory favors the view of psychopathology as representing an impairment in the formation of psychic structures that are analogous to the schema of social and cognitive psychology. This focus has spurred diagnostic efforts to evaluate the quality of these structures (self-system, object relations). Blatt (1991) assumed that the symptomatic manifestations of various forms of psychopathology are associated with different types of impairments of cognitive-affective structures in the representational world. For example, the growing consensus about the existence of two basic subtypes of depression (empty and guilty) is based on the phenomenology of experience associated with each. One type involves exaggerated preoccupation with issues of interpersonal relatedness, feelings of depletion, dependency, helplessness, or loss. The second type occurring later developmentally is associated with issues of self-definition, autonomy, guilt, and feelings of failure. The two types of depressed individuals change in various ways in the treatment process and are differentially responsive to different forms of therapy (Blatt et al., 1988). Wilson (1988) showed how each of these forms of depression is demonstrated differently on the Rorschach and TAT protocols. For example, stories told to TAT pictures with single characters that describe the person as empty, worthless, or helpless without introducing other characters exemplify the first type of depression. Such stories suggest that the narrator is dependent on what is immediately evident in the surroundings without being able to use inner resources to represent the support needed. The vulnerability to depression of an individual lacking such resources may be moderated by a supportive environment.

The profession is in need of a diagnostic system that identifies variables useful for the treatment process (Leve, 1995). Such a system would emphasize characteristics that interact with methods of intervention and, therefore, would serve as guidelines for their selection. The variables that Leve tentatively proposed are grouped into three categories: cognitive, environmental, and social-emotional. The cognitive and social-emotional categories include the following characteristics, among others: adequacy of causal reasoning, social-emotional reality testing, moral reasoning, ability to form and maintain close relationships, ability to identify and express emotions, as well as internal or external locus of control. Leve (1995) reasoned that cause–effect thinking is essential to the success of psychodynamic therapies since developing insight is part of the process. Cognitive treatments, however, do not require as high a level of causal reasoning because the therapist is more actively training the client either by explaining explicitly the causal connections or bypassing explanations altogether through giving behavioral instructions. Likewise, different therapies require different degrees of social intimacy for success, although all therapies have an interpersonal component. The interface of psychological variables and therapy processes need to be refined through further research. It is evident, however, that projective techniques can provide important data about these types of variables.

A fundamental consequence of schematic processing is the perpetuation of the schema in the face of conflicting evidence. Distorted schema that bias attention and information processing to conform to the original conception are related to psychopathology (Horowitz, 1991). The assessment of schema can guide psychotherapy by identifying these unconscious schematic distortions (Blatt, 1991). Bringing to awareness different schema of self (e.g., actual self, ideal self, ought self, dreaded self) and other resulted in positive therapeutic changes in both psychodynamic and cognitive therapies (Singer & Salovey, 1991).

The clinician needs a flexible repertoire of assessment techniques including projective methods because the information that each one provides is not equivalent. No method supplants or takes priority over others but contributes its part to the functional whole. The contribution of projective techniques is best addressed by looking at their place among other measures. The content and structure of responses to projective techniques can be compared with information from self and other reports. The problem-solving strategies and organization of ideas as expressed in projective responses can be compared with how these processes are expressed in more structured tasks. Each source of data is conceptualized according to its contribution to the cohesive patterns that include different levels of personality and variability in functioning under different conditions. A synthesis of these multiple layers permits more precise insight about functioning in various contexts.

Projective techniques clarify the organization and structure of the inner world. Their use is warranted whenever inner life and complex self-regulatory functions are important considerations, particularly when respondents are lacking insight or would be motivated to distort self-report. The task itself involves the utilization of previously organized knowledge structures to provide a response that is not well rehearsed. The linkages among the various elements of the response promote an understanding of the individual's organizational framework. Projective techniques add a unique dimension to the assessment by revealing the respondent's strategies for accomplishing the task and, at the same time, showing the content and organization of ideas that occupy awareness.

4.16.7 PROJECTIVE TECHNIQUES AS PERFORMANCE MEASURES OF PERSONALITY

The projective hypothesis implies that every human action and reaction bears the characteristic features of individuality (Rappaport, Gill, & Schafer, 1968). Therefore, projection is basic to every response process rather than specific to a certain set of stimuli. Essentially, any test is a performance measure designed as an analog to a life task. Projective devices are simply stimuli with known qualities that are used to elicit samples of behaviors that correlate with other behaviors.

The question has been raised about what aspects of responses to the Rorschach stimuli reflect compliance to task demands and what elements entail projection. Exner (1989) suggested that most responses are simply best-fit answers, and that projection on the Rorschach occurs only in responses that deviate from the norm or are elaborated beyond the stimulus field. This view assumes that projection on the Rorschach is an attribute of the response and not inherent in the task. Exner explains that projection is not encouraged by the instructions which simply call for answering "what might this be" nor by the blots which are not completely ambiguous. He points out that techniques such as the TAT force projection, by asking the respondent to develop a story that goes well beyond the stimulus provided. Yet, the story-telling task also makes problem-solving demands (Holt, 1961); the narratives are expected to be organized productions rather than fantasies or random associations. Just as identification of blot contours are expected to be guided by reality constraints, so do perceptions of emotions and relationships as well as the sequence of events in stories told to TAT stimuli.

Exner claims that the operations contributing to the formulation of responses to Rorschach stimuli such as scanning, encoding, classifying, refining, evaluating, discarding, and selecting are cognitive and not projective. However, in keeping with the projective hypothesis, individuals are expected to superimpose unique styles of organization on each of these cognitive operations. The distinction between problem-solving and projection is not an either/or, but a matter of relative emphasis. All projective tasks have problem-solving elements, and all responses are influenced by individual sets or internalized schema. Those who favor the projective viewpoint insist that such inner structures are fundamental to the response process. The conceptualization of the Rorschach as a perceptual-cognitive-behavioral task has been criticized on the grounds that this approach does not give sufficient weight to the role of stimuli from the inner world in the interpretation of stimuli from the external world (Willock, 1992).

As discussed earlier, projection is an ongoing process that comes to the fore if the situation is novel. In a routine, overlearned situation, individuals will respond with familiar, scripted knowledge. However, even a highly structured situation can be misinterpreted. When ideas on the more structured cognitive tasks are associative or disorganized, these cognitive difficulties will be magnified in responding to the less structured performance tests. One youngster who demonstrated serious problems in the application of rote knowledge in a relatively structured task also showed impaired thought process on the projective tests. To the Wechsler Intelligence Scale for Children (WISC III) comprehension item, "what would you do if you saw thick smoke coming from your neighbor's home?" he responded: "Stop, drop, and roll." This response was an association cued by some of the words in the item without understanding the entire question. The fire was in the neighbor's home, yet the child produced a rote response as if he were personally experiencing the fire. He had rehearsed this scenario at school, but was unable to apply the concept even under relatively structured conditions.

The capacity to organize the inner world and deal effectively with distracting thoughts, emotions, or motives should translate into the ability to tolerate and to deal successfully with ambiguity, complexity, and apparent contradiction in a variety of situations. Therefore, the experience of ambiguity and complexity may stem not only from reality demands but also from the individual's emotions and motives (Blatt, Allison, & Feirstein, 1969). A framework is needed for conceptualizing how projective techniques such as the Rorschach and TAT shed light on cognitions in ways that differ from more structured tests. Differences and similarities in task demands of various projective techniques also need to be understood.

The response to the Rorschach task involves the matching of ambiguous stimuli with a memory trace (Exner, 1993). The goodness-of-fit or perceptual match between the blot contours and the object reported constitutes the basic element of reality testing. When telling a story about a picture portraying one or more people, what is demanded is not simply perceptual matching required by the Rorschach task (Beck, 1981) but experiential matching. The narrator searches for a relevant explanation for the picture, then marshalls possible details from memory to satisfy the instructions and meet criteria for an acceptable story. If the stimulus is highly stereotypic, then finding an exact story from memory would be sufficient to accomplish the task. However, if the narrator encounters a picture that cannot be explained by existing schema, then the individual actively constructs the response and fills in details from various schema. Schank (1990) suggests that what exists in memory is a database of partial stories or story elements rather than whole ones. When telling a story to a pictured scene, the narrator draws on this database to construct a set of events and inner processes (characters' thoughts and feelings) that captures the gist of the stimulus.

All tasks are on a continuum of how much organization is required in making meaning of the stimulus and developing the response. The more open-ended the task, the greater the demand to construct the response actively rather than to respond in rote fashion to the stimuli. Therefore, projective techniques are particularly useful when adjustment to routine circumstances is good, but the individual is experiencing problems in less structured situations. Task by task analysis of the assessment battery permits the identification of the specific processes or competencies required for each task and the life situations to which these competencies can generalize.

A wide range of human ability lies outside the domain of standard cognitive tests. It is these competencies in the broad sense that are within the purview of projective testing. The primary advantage in regarding projective methods as performance measures of personality is that various tasks and measures can be differentiated in their demands. Generalization from one test performance to another and to real life performance then can be based on similarity of the demands. If projective techniques are treated as performance measures of personality, then it is possible to delineate task requirements, norms, and expectations about the product as seen with the Rorschach. In addition, it is possible to delineate linkages of that product with the acquisition of prior knowledge structures and with the application of these resources to similar problem-solving situations.

The term "*performance test of personality*" is proposed because it captures two key dimensions of projective techniques: (i) the problem-solving aspect of meeting specified performance expectations such as form quality on the Rorschach; and (ii) the organization of inner resources or schema brought to bear on the production. This dual approach to understanding projective techniques is shown in Table 1.

The distinction between self-report and projective measures has been described earlier. Self-reports ask the respondent to tell about the self, whereas projective measures require the performance of a task from which psychological processes are inferred. If we want to know how a person solves certain types of math problems, rather than ask the individual to report on how well he or she can solve linear algebraic equations, we would present some sample problems. Similarly, if we want to assess personality, we could obtain information through self-report by asking questions such as how flexible are you? How do you interpret cues in an unstructured situation? In contrast, we could request that the individual perform a task that demonstrates how various psychological processes are applied to meet the problem-solving demand.

Tests such as the Wechsler Scales are generally seen as measures of cognition, whereas the TAT and Rorschach techniques are tasks that are thought to reveal personality. This distinction is not entirely a function of the task but includes how the performance is evaluated. Human figure drawings, for example, have been used to estimate both cognitive level and personality functioning. The essential characteristics of tasks that measure personality, in contrast to cognition, are described below.

4.16.7.1 Total Personality

As do life situations, tasks vary in terms of the amount of structure, cues, or prompts provided for responding. As the expression goes, "It's not what you know but when you know it that matters." To be useful, knowledge structures must be spontaneously available when circumstances warrant. In the psychological test battery, personality performance tasks provide minimal guidance to meet the problem-solving demands and, thereby, permit the assessment of spontaneous strategies.

Generally, cognitive measures such as tasks on Wechsler scales do not reproduce the conditions encountered in everyday situations. Sternberg (1985) distinguished between analytic intelligence that is assessed by more structured tasks and practical intelligence. Analytic problems provide all necessary information and have a single correct solution separate from the emotional and social context. Real life problems are less clearly defined and typically call for information seeking. Note the following question on the WAIS-R: "In a movie theater, you are the first person to notice smoke and fire. What should you do?" The respondent is cued that the expectation is to do something. If this were a real situation, the person would not know that he or she was the first to see the smoke and fire. The person may not take responsibility with others around and, therefore, delay action. The individual may consider specifics of the context such as proximity to the fire, its size, or the availability of a fire extinguisher. However, the individual's emotional reaction may disrupt thinking. The actual response would involve the total personality, not merely the intellectual component.

The limitations on generalizing from responses to structured tasks to real life conditions are evident when we consider the attributes that these measures do not assess. These include being aware that a problem exists or that a task needs to be done; setting priorities and planning toward their implementation; pacing and self-monitoring; seeking or utilizing feedback; sustaining long term interest in independent activities; taking necessary risks; organizational skills; and recognizing and

Table 1 Task analysis of performance measures of personality.

Technique	*Ideal performance*	*Competencies needed*	*Inner life (how experience is organized and internally represented)*
Drawing	Symmetry, coherence, realism, match with instructions	Plan execution of drawings within allotted space and limits on drawing ability; organize details with context, handle frustration; investment in the task	Reality testing and quality of thought process; use of schema and organizational strategies; specific preoccupations or concerns
Narrative	Story matches picture and incorporates instructions, appropriate transitions and cause–effect connections; synthesis of various dimensions of experience within individual characters such as integration of inner life with external circumstances; balance among views and needs of all characters depicted; balance between excessive detail and vagueness; cohesiveness among intentions, actions, and outcomes; appropriate time perspectives	Draw on personal experience to construct a story that adequately explains the picture; modulate affects and recognize tensions depicted in the stimulus; organize, plan, and monitor details of story for cohesiveness and inner logic and for compliance with instructions; direct attention from one aspect of experience such as feelings to actions and outcomes; initiative to transcend the pictured cues to describe intentions and realistic, purposeful actions to resolve tensions; bring general abstract principles to bear on the task for optimal integration of multiple dimensions of the stimulus and coordination of inner and outer aspects of experience (thought, feeling, action, and outcome); investment in the task	Reality testing and quality of thought process; understanding social cues; strategies to organize experiences; specific preoccupations and concerns; nature of inter- and intrapersonal schema or scripts brought to interpretation of experiences and picture stimuli (experiential matching)
Inkblot	Accuracy and specificity in matching percept to form; organizing various components of the blots; balance among form and other determinants as well as between precision and vagueness in form definitions; logical and responsive communication during inquiry	Adequate investment in responding; realistic perception and organization of stimulus components; understanding of hierarchical relationships implicit in balancing form with other determinants; comfort with matching precision of percepts to relative imprecision of blots; confidence with ambiguous stimuli; systematic approach to the task	Reality testing; strategic processing of information and connecting new input with previously acquired sets or schema (perceptual matching)

Note: The task is somewhat different for each specific set of instructions and stimuli (e.g., draw-a-person in the rain vs. draw-a-person). Similarly, each Rorschach card and or TAT picture presents a unique stimulus configuration.

responding appropriately to subtle interpersonal cues. These attributes are traditionally viewed as pertaining to the personality domain and reflect the interplay of cognitive and affective processes. A response to the TAT involves the interpretation of the emotions and tensions depicted to recognize a problem, whereas a verbally communicated question or problem often contains cues to facilitate the response, and such cues may not exist in a real-life version of the scenario. Likewise, the Rorschach presents the respondent with options for interpreting the blot contours, organizing the percepts, and communicating them to the examiner.

4.16.7.2 Many Correct Solutions

Just as real-life dilemmas are amenable to diverse resolutions, personality performance measures can be approached in several ways. Therefore, many correct solutions are possible. Responses can differ according to the individual's interpretation of the stimuli and organization of the response. Variability, rather than uniformity, is the expectation with personality performance tasks. Rather than imposing specific criteria for correct responses, such tasks set a general expectation to deal with the stimulus realistically, follow instructions, and logically organize the response. In contrast, most cognitive tasks have one correct solution regardless of whether they call for rote knowledge or a more flexible application of prior knowledge. These distinctions between cognitive and personality performance tests are not absolute; various cognitive tasks share some common processes with personality performance measures. Reading comprehension, for instance, bears a resemblance to personality performance measures when previous sets influence the understanding of the text. There can be little argument about the facts presented in a passage, but individuals can justifiably differ to some extent on their inferences based on prior learning.

4.16.7.3 Generalize to Different Criteria

The distinction between typical vs. maximal performance (Cronbach, 1970) has been used to differentiate between personality and ability measures. This dichotomy contrasts responses to immediate cues and external motivating structures from performance that is regulated and maintained by the individual's long-term investment and initiative. A structured situation such as an achievement or cognitive test would generally tap maximum performance, but such performance generalizes only to similarly structured situations. Because most real life tasks provide less structure, measures of typical performance are also needed in a comprehensive assessment. Correlations are low between measures tapping maximal and typical performance (Sackett, Zedeck, & Fogli, 1988). Therefore, each provides unique information.

The following conditions were suggested by Sackett and colleagues as generally yielding estimates of maximum performance: (i) there is a heightened level of effort and attention because the task is seen as important; (ii) expectations and performance standards are clear; and (iii) the observation takes place over a relatively short time where the individual can exhibit an uncharacteristic spurt of effort that could not be sustained over the long haul. In contrast, the characteristics of measures of typical performance are as follows: (i) individuals are unaware that they are being observed or evaluated, so they are not trying deliberately to perform to the best of their ability; (ii) performance is monitored over a long period of time; (iii) the performance tasks require skills that have to be learned through continuous past efforts—if the task is highly complex, the individual has to bring a great deal of past learning (typical performance) to the current effort; and (iv) performance guidelines are not clear and, therefore, individuals impose their characteristic way of organizing and dealing with the situation.

Performance measures of personality meet several criteria for assessing typical performance. Prior knowledge (schema) is superimposed on current task demands; individuals are unaware of what aspects of their performance are evaluated; and in the absence of structure, they are required to organize and plan their response according to their typical mode of functioning. Understanding different requirements of different tasks helps explain variations in the assessment of similar constructs with different methods. Johnston and Holzman (1979) designated indices of thought disorder in the WAIS and the Rorschach which they tested with a sample of schizophrenics, their parents, and controls. The IQ score and the Thought Disorder Index (TDI) derived from the WAIS were negatively correlated such that the higher the IQ score, the lower the TDI. In contrast, IQ scores and the TDI derived from the Rorschach were uncorrelated. The authors conclude that the tasks make different demands. The WAIS calls for "habitual reactions and the social frame of reference is clear" (p. 61). The social expectations on the Rorschach are less obvious. Therefore, the task sets different requirements and has different implications for the assessment of impaired thought process.

In their sample of schizophrenics, those who were more intelligent were able to limit expression of disordered thinking on the WAIS more easily than on the Rorschach, in part, because WAIS items can be answered with overlearned responses. The feeling of ambiguity versus security determines efficiency of functioning on problem-solving tasks and in real life. Individuals who exhibit thought problems only on unstructured tasks may be more capable of functioning with the supports of structures and clear social cues.

A criticism of laboratory research has been that results do not generalize to nonlaboratory situations (Fromkin & Streufert, 1976; Snow, 1974). This is the case because precise linkages between processes engaged by laboratory activities and other life domains are not specified. Likewise, predictions from test performance to real life adjustment can be accurate only if they are functionally similar. By understanding patterns of strength and weakness across various tasks, the professional can point to areas where the individual can and cannot function adaptively.

4.16.7.4 Differences in Conditions of Learning and Performance

Responses to performance measures of personality, as most tasks, require previously organized knowledge and strategies. However, we distinguish between learning that is promoted by direct teaching (e.g., lecture, textbook) from learning mediated by the individual's synthesis of experience (Epstein, 1994). Personality performance tasks are guided more by self-regulated learning than by formal education. Again, this distinction in the conditions of learning does not apply in a dichotomous fashion to personality versus cognitive measures. For example, an individual's general fund of information is a joint function of direct teaching and the individual's interest and active, effortful processing of information. Depending on the individual, knowledge is acquired through some combination of direct teaching and self-regulated synthesis of experience.

Task requirements also differ on the basis of the conditions of performance. These conditions pertain to the spontaneous versus cued accessibility of prior knowledge and degree of organization required to produce the response. Cognitive measures that assess general fund of information often elicit previously acquired knowledge in piecemeal fashion (highly structured). Personality performance measures such as the TAT and Rorschach set conditions of performance that demand spontaneous accessibility to prior knowledge to interpret the stimulus and formulate the response according to the directions. The more open-ended the response, the greater the need for self-regulated strategies to organize the product.

Performance measures of personality maximize the imprint of organization so that the principles by which experiences are structured and the inner organization of the personality are revealed. A comprehensive assessment battery provides tasks that vary on the continuum of structure provided. Given such variation, it is possible to relate competencies required in each task to performance in life situations requiring similar competencies. This linkage is accomplished by understanding how processes exhibited during test performance are carried over to everyday functioning in various situations and incentive conditions.

4.16.8 SPECIFIC PROJECTIVE TECHNIQUES

Three basic aspects of projective techniques have been recognized (Rabin, 1981). First, the task entails the presentation of an ambiguous set of stimuli and a request to give an open-ended response. The Rorschach and TAT techniques include both of these stimulus and response attributes. Therefore, the focus of interpretation is on the perception of the stimuli presented and the organization of the response. Drawing techniques also demand open-ended responses but usually do not provide a stimulus. Second, the response is shaped by processes that are outside of conscious awareness. An important factor making the response less amenable to conscious manipulation (faking) is that the respondent does not comprehend the meaning of the answers given. Third is the complexity of the interpretive process. Each of these components is briefly addressed below.

4.16.8.1 Stimulus

In general, projective techniques present stimuli that are amenable to various interpretations, and instructions that can be addressed in a variety of ways. The degree of ambiguity has been a prime consideration, although other features of stimuli are also important determinants of the response. A systematic accounting of how the respondent uses stimuli is the essence of the Rorschach technique and must be given greater weight in thematic apperceptive methods (Henry, 1956; Teglasi, 1993).

4.16.8.2 Response

All projective tasks require the individual to draw on internal images, ideas, and relationships to create a response. The respondent must dredge forth past experiences, direct or vicarious, and organize them to meet the task demands. The greater the stimulus ambiguity and the more open-ended the response, the greater the reliance on the organizational structures of the personality rather than on rote knowledge. Yet, the stimulus must have sufficient structure to permit evaluation of the plausibility of the respondent's interpretation. The projective task demand is an analogue of other unstructured tasks and situations where available cues are subject to interpretation. The manner in which the individual interprets the stimuli and organizes the response shows how they will respond under similar conditions (Bellak, 1975, 1993).

Responses to projective tasks involve complex, interrelated processes that have conscious and unconscious components. These include the interplay of cognition-emotion-action tendencies that coordinate perceptions of the outward world with experience of the inner. Projective techniques may reveal aspects of emotion, motivation, and cognition that a person may not wish to expose. These unconscious aspects of responses may relate to issues of invasion of privacy. Faking, malingering, or defensiveness are problematic for any form of assessment but are assumed to be less so with projective techniques. However, the issue of fakability of projective tests has been inadequately investigated (Rogers, 1997).

4.16.8.3 Task Demand

The stimuli presented together with the instructions set the task demands (Teglasi, 1993). Projective techniques impose task demands that cannot be met with a simple response such as a request for specific information. They require respondents to apply what they know to produce a story or a drawing or to identify an object that may fit the ambiguous contours of an inkblot. Various projective tasks have features in common yet differ in important ways. Projective methods have been understood as problem-solving tasks with designated performance expectations as well as measures of personality with emphasis on individual variation.

4.16.8.4 Interpretation

The interpretive task is complex even when the scoring categories and interpretive guidelines are straightforward as in the Comprehensive System for the Rorschach. Despite the relatively clear guidelines and availability of norms (not to mention computerized reports), the Rorschach requires the examiner's trained inference along with the more objective coding. Interpretation is in keeping with the clinician's theoretical framework and understanding of the task demand. Therefore, the interpretation of responses to a projective test cannot be more satisfactory than the adequacy of the theory informing the interpretation of the evidence and the examiner's skill in evaluating that evidence.

The complexity of the interpreter's job is maintained because conclusions rest on the understanding of meaningful patterns rather than isolated response elements. Personality performance tests yield products where the whole is more than the sum of the parts. The evaluation of the response must account for the organization and cohesiveness of the different components. Therefore, various units abstracted from the whole cannot be treated in a piecemeal fashion. The more open-ended the response, the more amenable to separate analysis of structure, form, and style. Although these aspects of the response can be conceptually separated, their interpretive value lies in their relationship to the task demand and to each other. Content, for example, cannot be properly understood apart from the manner in which it is organized. Finally, the examiner must be aware of connections between empirical findings and theory to avoid speculation. Yet, empirical support of theory is not always conceptualized in ways that are useful in making decisions about one individual.

The sign approach attempts to provide empirical evidence for interpretations through the identification of features that occur most frequently in specified clinical populations. However, using a list of signs in an atheoretical cook book fashion is inadequate because a particular sign derives its meaning from the context of other responses. For example, in a TAT protocol, a stereotyped approach or meticulous listing of details in story telling may be viewed as resistance or as representing the respondent's best efforts. Likewise, concern with minutiae that most respondents disregard may be viewed as an index of hypervigilance or of concrete functioning. The appropriate interpretation depends on the pattern of responses within the story telling task and across tests in the battery.

Inferences are drawn from the clients' behavior during the evaluation as well as from the product. Any changes in demeanor or emotional reactions in response to the various tasks are noted as are spontaneous comments, time elapsed, expressions of uncertainty about performance, or attempts to seek structure. Aspects of the response process are also considered. These refer to the manner of working, compliance with instructions, sequence of ideas (e.g., planful, trial and error, organized, haphazard), as well as to dysfluencies, pauses, or hesitations. The product itself is amenable to analysis in relation to the process of the response, content, and structure. The formal or structural aspects of the product, of course, reflect the response process.

Next is a brief review of three major projective techniques in terms of the following elements: (i) task demands that include the stimuli and instructions; (ii) response process; and (iii) general interpretive approaches and issues.

4.16.9 THEMATIC APPERCEPTIVE TECHNIQUES

Apperception tests generally use pictures and standard instructions to elicit stories. The TAT (Morgan & Murray, 1935) is the most popular of these. Although introduced as a method to assess a particular theory of personality (Murray, 1938), this technique did not remain wedded to the theory of personality from which it sprang. The thematic approach described in the standard manual (Murray, 1943) was amenable to use with a wide range of scoring methods and has been adapted for clinical and research purposes. Spin-offs of thematic apperceptive approaches have used different picture stimuli and diverse scoring approaches. A variety of nonclinical coding systems for content analysis of the TAT appears in an edited volume by Smith (1992a). More clinically oriented systems also abound (e.g., Bellak, 1975; Cramer, 1996; Henry, 1956; Karon, 1981; Rappaport, Gill, & Schafer, 1968; Teglasi, 1993; Tomkins, 1947; Westen, 1991; Wyatt, 1947). Typically, clinicians have used the TAT by applying broad units of inference in an idiographic, qualitative manner. In contrast, researchers have scored TAT responses for various personality characteristics using specific and narrow scoring criteria. As of this date, there is no widely agreed upon scoring system for the clinical use of thematic methods. However, it is generally acknowledged that classification into diagnostic categories is not a chief purpose of the TAT.

4.16.9.1 Response

When given TAT-like pictures, the scene sets the topic. The story telling directions call for a description of what is happening in the picture, what happened before, what people are thinking, how they're feeling, and how everything turns out at the end. These instructions require the narrator to attribute thoughts, feelings, and motives to the characters depicted and embed these inner aspects of experience into an appropriate time frame and sequence of events that coordinate inner life with appropriate actions and outcomes.

4.16.9.2 Stimuli

Picture stimuli play a major role in determining the story content (Kenny, 1964; Murstein, 1965), and reviews of frequency of themes specific to TAT stimuli are available (Bellak, 1975; Henry, 1956; Holt, 1978; Murstein, 1968; Stein, 1955). Ambiguity was a primary consideration in designing the TAT stimuli (Murray, 1938). However, the degree of ambiguity varies within the set of TAT cards. The manner of defining ambiguity has ranged from judges' estimates of the number of interpretations that can apply to each card (Kenny & Bijou, 1953) to actual degree of variability in responses (Campus, 1976). Many of the TAT pictures clearly show who the characters are, what they are doing, and the emotions they are experiencing (Murstein, 1965). Yet, they permit a great deal of variation in the style of expressing similar themes. While stimulus ambiguity is essential to the projective hypothesis, other issues pertinent to stimuli such as similarity of main character(s) to the narrator, emotional tone, complexity, and latent meaning have been researched (see review by Teglasi, 1993).

Broad conclusions about the advantages of various degrees of stimulus ambiguity cannot be drawn without specifying the nature of the scoring system, population, and purpose. Low ambiguity has been favored in the assessment of specific motives (Singer, 1981). However, cards with high ambiguity have been preferred to measure the relative strength of two motives (Atkinson, 1992). When studying hostility, it was found that aggressive intent was most effectively measured by a picture with low relevance for hostility, whereas guilt over hostility was best measured with a picture of high relevance for hostility (Saltz & Epstein, 1963). The authors concluded that pictures with low relevance for unacceptable behavior such as hostility measure drive toward its expression, and those with high relevance measure inhibition or guilt about its expression.

Three degrees of ambiguity within the TAT set were estimated by a group of judges—high, medium, and low (Kenny & Bijou, 1953). The richness of personality content obtained varied as a function of card ambiguity. Cards in the medium ambiguous set yielded stories with the most personality information. The authors discussed two dimensions of ambiguity in card stimuli: (i) the number of cue constellations available to guide the response; and (ii) the definitiveness of the cues available. Sets of stimuli with graded levels of ambiguity permit the evaluation of responses to situations along a continuum of structure.

Studies of stimulus ambiguity are inconclusive because investigators compare various degrees of ambiguity that are not on the same points on the ambiguity dimension. Furthermore, conclusions about stimulus variables have generally been drawn regarding their adequacy to elicit content germane to the assessment of specific motives or relatively narrow psychological processes rather than their effectiveness to assess formal qualities of organization that reflect the respondent's capacity to deal with the task demands.

For clinical purposes, stimuli must permit the simultaneous evaluation of multiple psychological processes and analysis of both structural and content properties. Some clinicians argue that stimuli are relatively unimportant as long as they are not highly structured (Arnold, 1962; Karon, 1981). Criteria for picture selection within the TAT set are available (Bellak, 1975; Birney, 1958; Henry, 1956; Teglasi, 1993). Haynes and Peltier's (1985) survey of clinicians in juvenile forensic settings indicated that the mean number of cards used was 10.25. The most frequently administered TAT cards were similar to those deemed as most productive in previous studies (Cooper, 1981; Hartman, 1970). The TAT pictures have been criticized for being out of date in relation to clothes and hairstyle (Henry, 1956; Murstein, 1968) and for their predominantly negative tone (Ritzler, Sharkey, & Chudy, 1980). These concerns are mitigated by findings that the stimuli effectively permit expression of convictions and conceptualizations of affect. The negative tone presents unfinished business or a dilemma to be resolved and provides the opportunity to observe how the respondent interprets the tensions depicted in the picture. Furthermore, the negative scenes make it possible to observe how the narrator moves beyond the sadness or conflict to a more positive resolution by noting appropriateness of transitions between the negative state of affairs and positive outcomes. It has been suggested that pictures representing relatively universal social situations that most people encounter in their lives are suitable across various age and subcultural groups (Veroff, 1992).

4.16.9.3 Interpretation

Karon (1981) suggests that only a complex scoring system can be clinically useful. At the same time, "an adequate scoring system is so complex that no one has time to score the protocol" (pp. 94–95). Simple scoring systems are inadequate because they "throw away most of the information in the process of scoring, and hence turn out not to be clinically useful" (p. 95). This point is well taken. A multiplicity of thematic methods are available that provide carefully described scoring systems to assess relatively narrow aspects of personality. Although these systems have demonstrated a high degree of accuracy and reliability, their narrowness limits their clinical utility. Karon's remedy is to rely on clinical judgment in a sentence by sentence interpretation of the protocol, much like a clinical interpretation of an open-ended interview. This approach is compatible with the view that projective techniques are not tests, but are clinical tools that rely on the skill of the practitioner (Anastasi, 1976). An alternative is to agree on key psychological processes and guidelines for their measurement that may be time consuming to learn but less cumbersome to use once mastered.

Historically, there have been two ways to designate units of analysis for TAT stories: product centered versus narrator (person) centered. The former method focuses on qualities of stories that differentiate between groups; the latter approach emphasizes the psychological constructs to which attributes of stories relate. The narrator-centered approach permits the hierarchical organization of elements identified in stories in reference to broader features of the personality. For example, Rappaport, Gill, and Schafer (1968) organized story qualities according to affective lability and looked for content shaped primarily by affective responses to the picture. Holt (1958) looked at clarity of thought (vagueness, overgeneralization, disjointedness of organization) and emotional inappropriateness (arbitrary turn of events, forced endings). With such a focus on psychological processes, patterns of story elements can be organized in relation to relevant constructs.

Holt and Luborsky also emphasized adequacy of hero. This variable, however, is not a psychological process but a quality of the story considered important because it correlated with supervisor's ratings of overall competence during psychiatric residency training. Adequacy of the hero was subsequently viewed by Bellak (1975) as an index of the narrator's competency. However, this interpretation may not hold if other characters depicted in the stimulus or introduced in the story are helpless. This conclusion is also problematic if the narrator has not accurately incorporated the cues provided in the stimulus. A narrator-centered approach to this variable would focus on various psychological processes indicative of the story teller's competency. Three points are relevant here. First, no part of the story can be interpreted separately from the others. Second, the emphasis must always be on the narrator rather than the narrative. Third, the demands set by stimulus properties must be considered.

Emphasis on qualities of the narrator rather than of the product permits consideration that these qualities can be expressed in different ways. Therefore, the interpreter does not seek one-to-one correspondences but focuses on the fit between the pattern of responses and the psychological processes to which they pertain. For example, the assessment of a construct such as cognitive integration with thematic apperceptive methods may be accomplished by exploring the manner of interpreting stimuli or the manner of coordinating different dimensions of experience such as thoughts, feelings, and actions. More complex units, such as self-regulation, subsume cognitive integration as well as affective-motivational processes (Teglasi, 1993). Such a focus on the psychological processes of the narrator avoids the sign approach and promotes an understanding of the constructs being measured. This occurs by organizing story qualities in terms of a clear conceptualization of their relationship to relevant psychological variables. Conceptualizations of the psychological variables can undergo continuous refinement in keeping with research across various subdisciplines.

Form and content in the TAT have been distinguished (Henry, 1956; Holt, 1958; Teglasi, 1993). Formal features focus on generalized properties of content such as the organization and coherence of the response. These formal units of analysis refer to how the details of the content relate to each other, to the evoking stimulus, and to the directions given. For example, inferences can be made from TAT stories about striving for long range goals (independently of the specific goals or concerns) based on connections among characters' purposes, actions, and anticipated outcomes. Internal attribution of feelings is a formal quality because it need not refer to any specific feeling. These formal qualities of the story provide information about the cohesiveness and reality base of the narrator's schema rather than about specific concerns. They are akin to procedural knowledge within schema theory and should be evident across stimulus cards within a task and even across various projective tasks. Formal features of stories lead to inferences about the structure of personality such as cognitive integration, affect maturity, or self-regulation. Given that picture stimuli evoke specific content, it is these generalized or formal properties of content that can reliably reveal clinically important psychological processes.

A focus on the formal elements involves the following general principles of TAT interpretation.

(i) An organized narrative, not a patchwork of associations, is expected. The story is, therefore, evaluated in terms of how the narrator meets problem-solving task demands. The individual's problem-solving approach can be examined from two vantage points. The first focuses on how the story is told in relation to the stimulus and instructions. Accordingly, the narrative is evaluated in terms of accuracy in capturing the tensions depicted in the stimuli, compliance with instructions, and the logical and realistic unfolding of events. The second emphasizes how the characters are described in reference to the stimulus cues, the cohesiveness of inner states, actions and outcomes, as well as the manner in which characters define and resolve the dilemmas set before them in the stimulus.

(ii) Units of inference based on interconnections of elements such as the links between causes and effects or actions and outcomes pertain to formal characteristics of content. The content is not taken at face value. Instead, units of inference are based on understanding of psychological processes and task demands. The instructions call for inclusion of various levels or dimensions of experience such as thoughts, feelings, and actions. These human tendencies to think, feel, perceive, and act are interrelated, and interpretive meaning is derived from an understanding of their patterns. However, the narrator's understanding and the clinician's framework for conceptualizing such relationships must be clearly distinct (Cramer, 1996). The professional determines the implications of the narrator's understanding of the linkages among sequences of events, thoughts, feelings, behaviors, and outcomes.

(iii) The interpretation seeks patterns that elucidate the schematic structure connecting the various story elements (e.g., the manner in which self and other are differentiated and expectations about causal sequences). These schema are products of the synthesis of past experience and provide the templates for organizing current experiences.

4.16.10 RORSCHACH TECHNIQUE

The Rorschach has achieved wide acceptance due in large part to the development of the comprehensive system (Exner, 1993), an integration of previously established methods. The availability of normative data for discrete coding variables establishes psychometric credibility. In addition, the comprehensive system provides interpretive strategies for synthesizing the complex data and encourages the interpreter to move back and forth between the formal data of the structural summary and the content and language of the response.

The Rorschach administration is conducted in two phases. First is the association phase during which the respondent is shown each of 10 inkblots and asked "What might this be?" The inquiry phase begins after the respondent reports what is seen on each of the cards. The examiner guides the respondent to clarify the determinants of each response to permit accurate coding. Although the Rorschach is described as a cognitive-perceptual task (Beck, 1981), what is interpreted is what the respondent verbalized. Hence, the examiner must be well trained in coding and administrative procedures to avoid the many potential pitfalls of conducting an inquiry and to maintain the delicate balance between seeking sufficient clarification and promoting response sets by pressing too far.

4.16.10.1 Stimulus Features and Response Parameters

The structural approach to interpreting responses to Rorschach cards creates a close link between the stimulus qualities and parameters of the responses that are coded. Stimuli vary in the degree to which they are solid or broken, colorful or achromatic. They also display variation in shading, empty (white) spaces, and contours that are sufficiently familiar to evoke popular responses. Reported perceptions are coded according to patterns of attending to stimulus qualities including choices of blot areas and use of various features of the stimuli such as form, color, shading, hue, white space, card symmetry, or any combination. Also important are the accuracy of the match between the reported percept and selected blot contours and the relationships among the percepts (organization). Each code assigned to a response represents a particular psychological process. However, specific response elements such as choice of blot areas are interpreted in relation to other variables such as degree of organization in relating various blot areas. A response involving the synthesis of parts into larger units reflects more complex thinking than a vague, undifferentiated holistic perception of the card.

Perception of movement is not attributable to a quality of the stimulus which is static, but an imposition of the perceiver. It has been argued that phenomena such as movement are not perceptions (because blots are static, not moving) but mental constructions based on perceptual experiences (Blatt, 1992). In general, movement responses attempt to put greater specificity on form qualities. When such responses involve human activity, they often represent the individual's use of inner resources to modify perceptions of the external world. However, this interpretation changes if these efforts are combined with inaccurate form identification. If the forms identified differ greatly from those reported by others in a culture or society, then the individual is likely to make other people uncomfortable (without necessarily knowing why) by engaging in behaviors that depart from their expectations. Use of white space as figure-ground reversal is an analog to other figure-ground reversals such as an oppositional stance toward the world. Conventionality is interpreted according to the extent to which thought process is like others or different. The shading is a relatively subtle aspect of the Rorschach stimulus so that not all respondents report them as determinants (although they may perceive them). Such responses require a certain level of sensitivity or perceptiveness to verbalize.

The style of communication and nuances of language are important considerations (Smith, 1994). Therefore, characteristics of verbalizations such as redundancies or logical inconsistencies are noted. Even commonly reported responses can be expressed in unique ways. Percepts on the Rorschach are at times given without commitment or reflection, and the examinee might in such instances be reluctant to engage in the inquiry just as he or she was removed from the response process. These stylistic qualities of the response process provide a context for the interpretation of the variables in the structural summary.

Content given is also considered. For example, those who give a broad range of content have a greater variety of interests, and those who provide many human associations are exhibiting a broader interest in people. However, what is emphasized in coding responses is the manner in which the respondent uses the stimulus.

The Holtzman Inkblot Technique (HIT) (Holtzman, Thorpe, Swartz, & Heron, 1961) was designed to overcome what had been perceived as psychometric limitations of the Rorschach. Two parallel sets of inkblots were constructed, each set containing 45 inkblots plus two practice blots that are identical for both sets. The HIT was designed to differ from the Rorschach in several ways besides the number of inkblots (Holtzman, 1981). Two important differences are that the respondent is instructed to give only one response per card rather than leaving it open and that a short and restricted inquiry is given after each response. This overcomes criticisms of the Rorschach arising from the variations in the style of inquiry and from the widely varying number of responses obtained which make it difficult to use norms. However, abandoning the principles basic to the Rorschach also has disadvantages. One cannot observe whether the respondent can see something different in an inkblot once it has been identified in a particular way (flexibility), and the number of responses *per se* is an important consideration. Sequential analysis of multiple responses to the same stimulus is not possible in the Holtzman format.

Clearly, in devising variations on techniques, there are trade-offs that need systematic attention. Given such acknowledgment, clinicians can make appropriate choices.

4.16.10.2 Interpretation

The process of interpreting the Rorschach has distinct phases. First, the examiner codes the responses and organizes them into patterns by calculating the variables in the structural summary. These variables are then compared with norms to designate deviations from expected patterns. A strategy for interpreting the protocol is selected based on constellations of responses that depart from the norms. The final step involves the synthesis of the norm referenced response patterns according to the psychological process associated with them. This step also involves analysis of the details of content and of the quality of the verbalized responses. The comprehensive system provides clear guidelines for each step of the interpretation process (Exner, 1993), but the examiner integrates information from various sources to refine conclusions and formulate recommendations.

The comprehensive system began with an almost exclusive emphasis on formal, structural characteristics emphasizing the perceptual-cognitive nature of the task to match blot areas with objects (Weiner, 1994). However, language and other associations are considered important (Rappaport, Gill, & Schafer, 1968) and have become increasingly incorporated into the interpretive procedure (Exner, 1993). Smith (1994) cautions against acceptance of the Rorschach as a test with one correct method of interpretation. An exclusive focus on a single approach fails to acknowledge the potential contribution of those with a different perspective. Content interpretation including recent attempts at codings of object relations (Lerner, 1992; Stricker & Healy, 1990) is difficult to reconcile with the emphasis on structural variables. Historically, these two types of data have been viewed through different theoretical perspectives. An alternative suggested by Weiner (1994) is to focus on distinctions within personality rather than on classes of data such as form versus content.

4.16.11 DRAWING TECHNIQUES

Drawing tasks do not provide a stimulus but do exhibit the dual nature of projective devices as problem-solving tasks that reflect internal representations. Drawing a person or a family requires the translation of a three-dimensional memory image into a two-dimensional graphic representation within the constraints of the respondent's artistic ability. This conversion of three dimensions into two and compliance with instructions are the chief problem-solving task demands. Performance of the drawing is affected by the conceptualization of the object drawn, motor execution, attention to detail and spatial relationships, as well as planning and organizing the production. Like other projective tasks, the drawing can be evaluated according to its structure (proportion, elaboration, consistency of detail), content (what is drawn), and style (line pressure, size, placement). Machover (1949) suggested that structural or stylistic elements of size, placement, quality of line, positioning, symmetry, elaboration, or shading are more reliable than contents such as body parts and clothing. Performance standards for drawings can be set such as respect for inside and outside boundaries of the persons drawn and coherence and balance among details. A stylistic quality such as perfectionism and frequent erasures can be compared to the eventual quality of the product. The sheet of paper sets the boundaries or limits for the drawing. Very small or very large drawings suggest that the individual has difficulty setting boundaries in relation to the environment. However, other influences such as impaired psychomotor functioning (e.g., arthritis) in older clients (Kahana, 1978) must be acknowledged. Furthermore, processes such as lack of planning contribute to the use of available space. The individual may draw a head that is too large (lack of planning) so that the drawing either is out of proportion or cannot be completed on the page.

Drawings have been used to estimate intellectual functioning and neurological status as well as to assess personality. The draw-a-person Test (DAP) widely used as a projective technique to assess personality (Machover, 1949) is also used to measure mental development (Goodenough, 1926). Its usefulness as an indicator of concept formation (intelligence) in the developing child was based on how closely the drawing approximated life-like proportions and details. Basically, the degree of realism was the criterion reflecting the child's conceptualization of the outward world through correct depiction of space and perspective. The Goodenough (1926) Draw-A-Man Test and the Harris (1963) revision of some criteria included items that appeared more frequently with increasing age. However, even as emphasizing age related trends, Goodenough (1926) noted the following individual variations in drawing that were not linked to development: (i) detail dominated but with few ideas; (ii) unique depictions that seem comprehensible only to the drawer; (iii) suggestive of a flight of ideas; and (iv) contradictory combination of primitive and mature characteristics.

Koppitz (1968) also differentiated qualities of children's drawings that were not a function of age. These aspects of drawings were stylistic: (i) qualitative aspects of integration, symmetry, and shading; (ii) presence of unexpected characteristics; and (iii) absence of expected characteristics beyond various ages. These qualities were viewed as manifestations of concept formation that were impacted by motivational and emotional aspects of the personality rather than chronological development. Drawing tasks are frequently given to adults to assess neurological status based on the observation that brain damage interferes with the integration of spatial, perceptual, and motor responses needed to execute drawings (Swindell, Holland, Fromm, & Greenhouse, 1988; Mendez, Ala, & Underwood, 1992).

Currently, the most frequently used projective drawing technique is the Draw-A-Person (DAP) as developed by Machover (1949) and expanded by others (Hammer, 1958; Handler, 1985; Koppitz, 1968, 1984; Urban, 1963). Also popular are the kinetic family drawing (KFD) technique (Burns, 1987; Burns & Kaufman, 1970, 1972); and House–Tree–Person (H–T–P) drawing task (Buck, 1948, 1987).

4.16.11.1 Interpretation

The dichotomy between person centered and product centered interpretation mentioned earlier is relevant here. Person centered approaches organize aspects of the production according to relevant psychological processes of the client. The interpreter looks for coherence in form, content, and style of the production with the hypothesized psychological variables. The professional also notes consistency with drawing instructions, nature of verbalizations about the figures drawn, and the amount of effort expended. Global interpretations of interrelated parts are more valid than isolated interpretation of specific details. The sign approach to validating drawings has been criticized (Kahill, 1984; Roback, 1968; Swensen, 1968) because there are multiple possible interpretations for any quality, depending on the overall pattern. For example, size and detail of drawings can signal preoccupation, differential valuing, conflict (Fisher, 1986) and/or quality of planning and organization. Similarly, qualities such as shading or erasures are said to signal anxiety. However, the nature of the shading is important since this feature may enhance artistic quality and not reflect anxiety. It should also be noted that people differ widely in how they cope with anxiety. Some anxious individuals will race through the task without shading or erasing. If the focus is on the psychological processes of the individual, then the configuration of response elements or signs would be expected to cohere around that process.

It has been suggested that the clinician ask what a particular sign could mean rather than what it does mean (Handler, 1985). A critical review of the literature on the KFD technique (Handler & Habenicht, 1994) emphasized the need to study more holistic, integrative approaches to the KFD rather than the interpretation of a series of single signs. The authors argue for the importance of focusing research on the interpretive approach of the clinician using the KFD rather than on the technique itself. The use of drawings for multiple purposes (e.g., concept formation, neurological status, or personality) demonstrates the multidimensional aspects of projective tasks which permit simultaneous evaluation of responses from multiple perspectives to reveal various interrelated facets of functioning. Broad performance expectations pertaining to structural features of the product can be delineated. As with other performance measures of personality, individuals are free to vary their approach to meeting these general problem-solving expectations. One caveat is that artistic quality of the drawings appears to influence clinician's interpretation (Feher, VandeCreek, & Teglasi, 1983).

4.16.12 CASE ILLUSTRATION

On the surface, the three projective techniques reviewed seem very different. Yet, they reveal similar information when compared in terms of structural qualities. The overlap between the TAT and Rorschach is illustrated by comparing formal aspects of Carl's TAT stories with conclusions drawn from the Rorschach. Carl, a 19-year-old man, had stopped attending school on a regular basis after the seventh grade and left school altogether during the 10th grade. At the time of this evaluation, Carl was incarcerated and attempting to continue his education in prison. He was doing poorly in his classes and was referred to determine if he would qualify for special education services. His WAIS-R IQ score was low average. The intent here is not to develop a comprehensive clinical picture but to point out the overlaps between the two projective techniques. Table 2 shows the consistency of the TAT variables across cards and also displays the relevant Rorschach data.

> *Card 1.* Little boy thinking, he's thinking how. I guess he's thinking a way how to work the violin. (Before?) He don't know how to work the violin. (TO?) Turns out he's still sitting there thinking.

Table 2 Corresponding aspects of Carl's TAT stories and Rorschach variables.

	Card									
TAT variables	1	2	3	4	5	6BM	8BM	12M	13MF	13B
Imprecise accounting of the stimulus		X	X	X		X	X		X	
Vague, concrete, or stereotypic story	X	X	X	X	X	X	X	X	X	X
Requires more than one query	X	X	X	X	X		X	X	X	X
Story ending is concretely tied to the stimulus	X	X	X	X	X	X	X	X	X	X
Relationship among characters are unclear, stereotypic, or unstated	NA	X	NA	X	NA	X	X	X	X	NA
Sense of helplessness (e.g., inaction, when it is warranted; lack of initiative or inertia)	X		X	X	X	X		X	X	X
Inner life such as intentions for actions or feelings is not sufficiently elaborated	X	X	X	X	X	X	X	X	X	X
Implausible sequence of events (e.g., cause–effect, timing, coherence of action with purposes)	X	X	X	X	X	X	X	X	X	X
Focus is dominated by the immediate circumstance or consideration	X	X	X	X	X	X	X	X	X	X
Insufficient integration of detail to comply with instructions	X	X	X	X	X	X	X	X	X	X

The boy in the story can only keep sitting there thinking how to work the violin. He does not have sufficient resources to deal with the task or to find alternatives. Likewise, the narrator cannot go beyond the picture cues provided (concrete) to produce an ending or to describe purposes or deliberate actions. When prompted to tell what happened before, the response (didn't know how to work the violin) stayed within the moment without considering larger purposes. The fact that the narrator does not introduce other characters to garner support is consistent with the absence of human content in the Rorschach. The helplessness displayed by the character and the narrator is consistent with the positive Coping Deficit Index (CDI) on the Rorschach, suggesting insufficient resources to formulate responses to demands. The short and simplistic story is devoid of inferential or interpretive processes as consistent with vague and concrete information processing on the Rorschach (Lambda, Zd, DQ+, DQv, W:M).

> *Card 2*. The man in the field working. Lady holding onto the stump because she looks like she's pregnant. Girl just come home from school. (T&F). Probably thinking about all the work they gotta do. And the man and the girl probably feeling the same pain, or sorta, for the lady that's pregnant. (Before?) The man started working. (TO?) Everything got done.

The story is closely anchored to the stimulus, yet the narrator does not give priority to the young woman in the foreground, nor does he indicate how the three people are related. Connections are vague and concrete such as the description of the lady as holding on to the stump because she's pregnant. Characters are differentiated only by external appearances, and they all feel the same. As in the previous story, inner life is not elaborated. Carl's Rorschach record contains no human movement, a variable that is associated with greater acceptance of inner thoughts and greater interpersonal awareness. None of the TAT stories suggests the availability of these resources.

> *Card 3*. Little kid was probably tired so he or she fell out the chair. (T/F?) Maybe, I guess they think that's where they gonna sleep at. And probably feeling stupid because he's on the floor. (TO?) That's where they gonna be.

The character falls because he's tired and, despite feeling stupid, just stays there. Again, there's no purposeful action or inner resources but an inertia that's consistent with vague and insufficient processing of information. Feeling stupid, yet doing nothing, is consistent with low self-worth shown on the Rorschach. Other Rorschach variables suggest that self-perceptions are naive and not guided by insight (no FD, no H) nor are these perceptions accompanied by dysphoric mood, anger, or irritation.

> *Card 4*. Lady trying to convince her husband that she love him, but he ain't trying to hear it. (Before?) They was fussing, probably. (TO?) He's about ready to walk away.

The story shows no attempt to understand the inner life or concerns of others but indicates detachment from relationships. The explanation of the stimulus is incongruous—the man looks very angry, but his wife is declaring her love. When asked what happened before, the couple was described as fussing, but the nature of their disagreement is unstated. The picture shows the man turning away, and the narrator does not have the inner resource to provide a solution to the conflict that departs from the stimulus. The Rorschach also suggests that social relationships are superficial, distant, and guarded. The oversimplifying style is likely to lower sensitivity to the needs and interests of others, and this tendency is coupled with a lack of interest or detachment from relationships (no H; no COP or AG). The affect cluster suggests an approach to the environment that minimizes affective engagement. Lack of resources rather than affective provocation is at the heart of Carl's difficulties. His reluctance to process emotional stimuli (Afr) is consistent with his general style of oversimplified processing of information (low blends, high lambda, under-incorporating approach).

> *Card 5*. The lady must have heard someone in the house, so she ran and hide in the closet. (T/F?) She probably thinking that she gonna get hurt. (TO?) That no one was there.

The woman runs and hides because she feels vulnerable. Later, when she realizes there's no danger, she makes no attempt to discover the source of her concern (noise). This absence of initiative and curiosity is consistent with non-reflection, simplified processing, and detachment evident in the Rorschach as described previously.

> *Card 6BM*. Looks like his mother told him some bad news. But the news didn't only hurt him; it hurt both of them. (TO?) That something did happen.

Again, the story offers vague, nonspecific descriptions such as bad news and little differentiation between characters. Since the nature of the bad event is not understood, it is not possible to deal with it adaptively. The absence of specific story details is consistent with the other cards and with vague, simplified processing suggested by the Rorschach. The story ends with the character convincing himself that something did happen.

> *Card 8BM.* Looks like they was trying to rob the lady, and she shot one of them. And the man's two buddies trying to get bullets out of him. (T/F?) Probably thinking that he ain't gonna make it. (TO?) That he made it.

The story presents an unrealistic sequence of events and poor integration of foreground and background components of the picture. There's no reasoning about intentions or consequences. Rather, the narrator gives simplistic associations to the stimulus without rule governed connections among likely sequences of events, between causes and effects, or between short and long term outcomes. This detachment from conventional thinking is consistent with poor reality testing on the Rorschach (poor form quality, low populars, incomplete processing of available information).

> *Card 12M.* This is a lady? (It can be whatever it looks like to you) The old man is praying for the lady because he thinks that if he prays, she'll get better. (Before?) She was sick. (TO?) That she didn't make it.

As with the other stories in this protocol, the story does not depart from the immediate cues of the stimulus. Connections between sequences of events and among characters depicted are vague or nonexistent. For example, we do not know what is the relationship between the old man and the lady. The narrator is powerless to introduce alternatives that are not cued by the stimulus such as consulting a physician. The lack of integration and insufficient organization of details is consistent with Rorschach patterns suggesting that Carl formulates decisions without sufficient processing of information (e.g., high lambda, low developmental quality, low blends, and underincorporating style).

> *Card 13MF.* The old man just got up for work, but his wife didn't have breakfast made for him. (T/F?) One of them feeling really tired. The other feeling left out. (TO?) Turns out that one of them sleep and one of them woke.

This story is also rather concrete and stereotypic. Each character has his and her roles to play, but the narrator cannot develop the story beyond what is seen in the stimulus (reliance on immediate external circumstances).

> *Card 13B.* Little boy ain't got no friends and wants something to drink bad. (Before?) Just sitting there. (T/F?) I guess he thinking why he's the only one there. (TO?) That he wasn't.

Just as in Card 5, the ending contradicts the initial premise of the character. Things are not the way they seem, but there's not enough initiative to investigate or deal with the discrepancy. Such lack of investment in processing information is compatible with the failure to process critical cues (underincorporation) on the Rorschach. Again, no purpose, interpersonal connection, or guiding principle is expressed.

The similarity of the conclusions derived from both techniques suggests that they are assessing common processes. Both methods suggest that resources and reality testing are not adequate to meet daily life demands. Furthermore, the focus on the immediate and the concrete, along with haphazard processing of information, hinder the development of schema that are sufficiently elaborated to provide rules that govern the synthesis of experience, the regulation of behavior, and the expression of affect. Without such inner guides to self-regulation, Carl exhibits tendencies toward impulsive, antisocial behavior and has limited capacity to delay gratification. Carl would benefit from a highly structured learning environment with highly structured tasks and frequent feedback and redirection.

4.16.13 VALIDATION ISSUES

Major criticism has been directed not only towards projective methods but also towards psychometric approaches to assessing personality which classify instances of experience, thought, or action into trait categories. The inference process, in general, has been maligned by the behaviorist movement. Compelling arguments have been made to exclude from consideration anything but overt behavior and objectively coded environmental variables (Skinner, 1953). Psychology has moved far from that position to a recognition of the importance of understanding the meanings that individuals assign to environmental events and to their own behaviors. Indeed, cognitive structures and processes are now considered to be at the heart of individual differences in experience, thought, and action, both adaptive and maladaptive (Cantor & Kihlstrom, 1987).

The process of inference is not restricted to the use of projective tests—it is what makes the psychologist a professional rather than a psychometrist. By giving priority to some scores or using qualitative information to increase understanding of the scores, the clinician engages in the process of making professional judgments (Groth-Marnat, 1990). These judgments cannot and should not be eliminated. It is important, however, for practitioners to reflect on the quality of their inferences and the usefulness of their decisions.

Evidence for validity of conclusions made on the basis of inferences drawn from projective methods needs to be convincing. Absolute standards that cut across all methods are essential and they must be precise enough to inform judgments about when the standard is or is not being met. However, in their application to projective techniques, general criteria should accommodate to the nature of the method. Validity and reliability are not established for a generic technique such as figure drawings, the TAT, or the Rorschach. Rather, the utility of each set of instructions and stimuli together with the scoring method is separately evaluated according to the accomplishment of its specific purpose. Ways of demonstrating validity and reliability for all techniques must be in tune with the logic and coherence of the measures and constructs under consideration.

4.16.13.1 Reliability

Establishing reliability for projective techniques and for questionnaire methods is fundamentally different. As Kelly (1958) pointed out: "When the subject is asked to guess what the examiner is thinking, we call it an objective test; when the examiner tries to guess what the subject is thinking, we call it a projective device" (p. 332). Reliability of items on a rating scale is essentially a matter of consistency in the respondent's interpretation of the items. Reliability of inferences based on projective methods rests on a combination of the stimulus, the response, the method of interpretation, and the skill of the interpreter. Psychometric procedures to establish reliability based on forced-choice test items can be carried out without any clinical expertise because reliability pertains primarily to the test-takers responses. With projective measures, reliability, in part, is an attribute of the interpreter because the scoring units are inferences of the professional. Attempts to designate cookbook procedures so that the validation process can be carried out quickly and easily are out of tune with the nature of projective methods.

The following is a brief overview of how traditional psychometric indicators must be modified to establish reliability of projective techniques:

4.16.13.1.1 Scorer reliability

The accuracy of two people looking for the same information requires adequate training and clear guidelines. When raters are well-trained and scoring systems are well documented, such reliabilities tend to be high. A related aspect of scorer reliability, particularly relevant to clinical inference is the consistency with which one rater codes the same protocol over time (Karon, 1981).

4.16.13.1.2 Decisional reliability

The consistency of decisions drawn from a protocol can be assessed when specific units are not the focus. For example, Shneidman (1951) showed that 16 clinicians using their own methods came to similar conclusions. Other influences on the reliability of decisions may relate to the number of performance samples needed. For example, in the measurement of particular motives with TAT cards, it is important to know if the specific motive emerges reliably in every card or only some. To assure adequate reliability, it has been recommended that at least six stories be obtained from each respondent (Lundy, 1985; Smith, 1992b).

Decisions must be based on clear conceptualizations. Therefore, decisional reliability must account for the theoretical appropriateness of the match between predictor and criteria. Test responses can be expected to correlate with criteria only if their meaning is functionally similar. Thus, adequate functioning in a structured situation can occur despite disorganized responses on a projective test.

4.16.13.1.3 Test–retest reliability

One important factor in demonstrating the reliability of the measure upon retesting is whether one is looking for similarity of content or of the inference (Karon, 1981). The reliability of the specific content is less relevant than consistency in the meaning of the response.

4.16.13.1.4 Internal consistency

Internal consistency of thematic content across cards would be an inappropriate measure of reliability because cards are designed to elicit different themes (Lundy, 1985). However, despite variability in specific content, the responses may yield similar inferences. More stylistic units representing psychological processes such as the accuracy with which the content captures the "gist" of the scene presented or linkages between causes and effects may be generalizable across different stimuli. Internal consistency based on the number of words per story (alpha = 0.96) was much higher than internal consistency of need for achievement (Atkinson, Bongort, & Price, 1977). Likewise, Rorschach cards present stimuli with important differences and, rather than estimating internal consistency, inferences are made on the basis of the entire coded protocol and not card by card. Responses to the white spaces in the blot have different meaning for each card, and not all white space responses represent figure ground reversal. Therefore, adding all space responses is a rough estimate of the trait in question.

Internal consistency expected within a measure should relate to the nature of the task and to the consistency inherent in the construct under consideration.

4.16.13.2 Construct Validation

Messick (1989) defines construct validity as "an integration of any evidence that bears on the interpretation or meaning of test scores" (p. 17). Because traditional indices of content or criterion validity contribute to the meaning of test scores, they too pertain to construct validity. Thus, construct validity subsumes all other forms of validity evidence.

This emphasis on construct validity as the overriding focus in test validation represents a shift from prediction to explanation as the fundamental focus of validation efforts. Construct validation emphasizes the development of models explaining processes underlying performance on various tests and their relationships to other phenomena. Accordingly, correlations between test scores and criterion measures contribute to the construct validity of both predictor and criterion. In Messick's words, "Validity is an integrated evaluative judgment of the degree to which empirical evidence and theoretical rationales support the *adequacy* and *appropriateness* of *inferences* and *actions* based on test scores or other modes of assessment" (p. 13).

4.16.13.3 Multitrait, Multimethod Validation

Although the multitrait, multimethod approach is a standard technique for construct validation (Campbell, 1960; Campbell & Fiske, 1959), this technique is vulnerable to problems with the definition and measurement of constructs. This procedure seeks to establish higher correlations across diverse measures of the same trait (convergent evidence) and lower correlations among similar measures of different traits (discriminant evidence) to show that a construct is distinct from other constructs and that it is not uniquely tied to a particular measurement method. Yet, the possibility that the constructs may indeed be tied to the measurement tool must be considered. McClelland and colleagues showed that attempts to correlate self-report and projective measures of achievement motivation to validate either one are misguided. Likewise, Horowitz (1991) notes that schema, although important to measure, are not directly known by the subject and cannot be confirmed through self-report but by a consensus of two or more independent observers. Theoretical understanding of the construct must always be central to the choice of validation efforts.

It is important to acknowledge the potential for corroboration of constructs with various assessment measures. Yet, different measures of the same construct (e.g., ratings by actor versus observer) may be assessing qualitatively different aspects of that construct. Meaningful differences in the constructs are demonstrated by distinct patterns of relationships with various criterion measures (see criterion validation below).

Even highly similar measures (e.g., thematic approaches) used to assess identical constructs but with different procedures are not necessarily addressing the same qualities. For example, Arnold (1962) developed criteria for scoring TAT stories for achievement motivation by comparing groups of individuals known to differ in their job success. In contrast, the McClelland–Atkinson tradition (McClelland & Koestner, 1992) for developing criteria for scoring achievement motivation from stories told to picture stimuli was based on the comparison of groups given different instructional sets to arouse the achievement motive. Each of these two approaches to contrasting groups may be appropriate for given purposes with specific populations but clearly involve distinct conceptualizations of the achievement motive. One takes the position that the motive is present and, when aroused, energizes and directs behavior towards a particular class of goals or incentives. The other focuses on the achievement motive as being a relatively stable disposition reflected by complex patterns of cognitive–emotional processes that guide perceptions and behavior. If scoring units are empirically derived through contrasting groups, then the construct is defined by the nature of the groups and procedures used.

4.16.13.4 Criterion Validation

Criterion related evidence also belongs under the rubric of construct validity (Messick, 1989). Patterns of correlations with other variables contribute to the defining attributes of each construct. The same set of external correlates do not apply to achievement motivation measured through projective and self-report methods (Spangler, 1992). Projective measures of achievement motivation correlate with spontaneous effort sustained over time, whereas self-reports correlate with activities that are cued by the situation. Such variation in the match between the predictor and the target clarify the dimensions of the achievement motive assessed by each type of measure. This understanding of constructs in terms of the life conditions to which they generalize constitutes the simultaneous validation of the predictor and the criteria. Relationships between predictors and criteria derived from a construct must be tested for expected patterns of discriminant and convergent evidence. In doing so, both situational specificity and generalizability of constructs and their measures are addressed at the same time. Generalizability of the predictor–criterion relationships across different population groups, settings, task domains, ages, or gender must be empirically established.

4.16.13.5 Part–Whole Relationships

Personality is a functional whole comprised of patterns of interrelated components. Therefore, predictions from single elements of personality to more encompassing units, such as general adjustment, proceed from part to whole and can only account for a portion of the variance. This part–whole prediction is illustrated in Figure 1 showing the influence of temperament on adjustment as mediated by goodness-of-fit. Any one temperamental attribute would account for a small proportion of the variance in the fit between the person and various situational contexts or task demands. A configuration of such traits would improve the prediction. However, the actual goodness-of-fit would be a better predictor of adjustment because this broader construct subsumes the configuration of traits (even those not specifically addressed in the prediction), the environmental demands and supports, as well as coping mechanisms.

This understanding of the part–whole relationship is essential for the validation of projective techniques. Projective techniques look at individual differences at a more global level than other measures. The products reflect schema or inner structures that develop through the individual's synthesis of life experiences. These involve the interplay of all of the person's characteristics and reciprocal transactions with the environment. Therefore, part–whole patterns exist between various trait constructs and response parameters within the test. Part–whole predictions can relate specific neuropsychological or temperamental processes to individual differences in responses to projective tasks (Bassan-Diamond, Teglasi, & Schmitt, 1995). Part–whole relationships depend on conceptualizations about how the various dimensions of individual differences come together in the development of broader units of personality such as the influence of temperament on conscience development (Kochanska, 1993). Given the expected role of multiple variables, it is apparent that expectations about the size of correlations need to be in line with understanding of the phenomena.

The part–whole issue also applies to the relationships among responses within a specific projective technique. The functional significance of each part hinges on its interplay with other parts in relation to the constructs being considered. Various dimensions of the product such as form and content variables are cohesively related and need to be systematically coordinated into higher-order constructs. Psychometric and theory-based approaches need to be integrated to build useful frameworks for clinical use. Specific response parameters can be abstracted from the whole and pieced together to find conceptually meaningful patterns.

4.16.13.6 Convergence of Psychometric and Conceptual Treatment of Data

Normative, nomothetic, and case study approaches to data collection are interrelated. Conceptual linkages among these approaches are essential to the interpretation and validation of projective techniques, as described next.

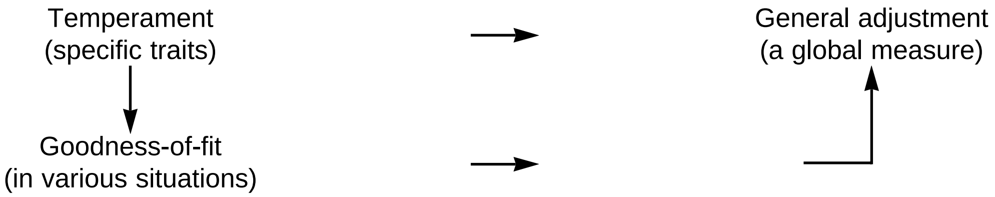

Figure 1 Illustration of part–whole prediction.

4.16.13.6.1 Normative

Before initiating the arduous process of collecting norms for projective methods, the units of analysis must be conceptually meaningful, theoretically relevant, and clinically useful. Furthermore, criteria for coding must be provided in sufficient detail to assure rater reliability. The Comprehensive System for the Rorschach has shown that the establishment of norms for meaningful units of analysis is possible, and that larger conceptual units can be designated through the use of multiple cutoffs to establish interpretively useful patterns of interrelated response parameters.

4.16.13.6.2 Nomothetic

It is important to base norms on units of interpretation that represent psychological processes that can serve as explanatory constructs. The nomothetic approach attempts to promote conceptual understanding through the study of general principles and functional relationships among variables. Such a conceptual approach to the Rorschach (Blatt & Berman, 1984; Weiner, 1977) has advocated organizing discrete response parameters into theoretically relevant clusters that contribute to a well defined construct. A strict empiricist would be satisfied with the prediction of patterns of behavior from various configurations of test responses (e.g., of Rorschach variables). However, establishing such empirical relationships is only a starting point for building conceptual frameworks for understanding and explaining behavior. The meaning of test response patterns emerges from a network of relationships with other theoretically relevant response patterns and theoretically appropriate external criteria.

The collection of normative data for projective techniques is embedded in the construct validation process. The constructs and units of inference for projective measures need to be defined *a priori* in the same way that test items in questionnaires are selected to represent constructs. An example of this approach is the designation of units of inference for TAT stories on the basis of constructs derived from research and theory on empathy (Locraft & Teglasi, 1997). Scores based on these units subsequently differentiated groups of children designated as high, medium, and low on empathy on the basis of teacher ratings. Such units require cross validation on numerous populations to assure wide applicability prior to attempting large scale normative studies. Unless the unit of inference is conceptually clear and represents meaningful psychological processes, normative data or group comparisons are not particularly useful.

4.16.13.6.3 Case study

The case study is most relevant to the practicing clinician because decisions for clinical purposes relate to understandings about one person. The adequacy of these decisions can be validated on a case by case basis. Although case study methods focus on the unique patterns of variation in responses of a single individual, the pattern of variables under consideration can be referenced to norms and to theoretical constructs. With projective methods, the respondent is allowed free expression within a specified context (stimuli and directions), and effective use of these techniques require a conceptual framework at three levels. First is an understanding of the psychological meaning of the response patterns within the projective measure. Second is an understanding of how the projective measure fits with other information in a comprehensive evaluation. Third is a conceptualization of how the patterns relate to competencies needed in the relevant life situations. Therefore, to conduct adequate case studies, the examiner needs a framework to understand how various types of data fit together within and across measures and how the emerging patterns apply to the various demands of the individual's environment. The attempt to integrate psychometric (empirical) and nomothetic (theoretical) data into the case study is typified in the attempt to synthesize structural and content features of Rorschach responses (Erdberg, 1993). The problem is that these efforts have applied different conceptual frameworks to different aspects of the data. A true integration of the empirical and theoretical perspectives requires a focus on personality constructs and the establishment of coherent patterns of data from various sources around the constructs.

The term "conceptual validity" has been applied to the process of psychological assessment (Maloney & Ward, 1976). Whereas construct validity focuses on confirming expected patterns of relationships across individuals, conceptual validity focuses on observing cohesive patterns within an individual. These patterns of expected relationships among observations constitute a working model of the individual being evaluated. According to Maloney and Ward, establishing such a model is a prerequisite for answering the referral question. When information from various sources is understood in terms of the constructs that explain an individual's difficulties and point to appropriate decisions, the assessment has conceptual validity.

4.16.14 FUTURE DIRECTIONS

The anticipation of future directions for projective techniques emerges from the clues gleaned from the scientific literature pertaining to the development and assessment of personality. However, the prognosticator's wishful thinking also influences this process. The intent of the prognosticator is to show how unfolding trends or even new spins on old ideas point toward desired alternatives for moving forward. Future possibilities for projective techniques are drawn from three conceptually distinct perspectives: (i) converging constructs from the various subfields of psychology that scaffold the use of projective techniques; (ii) refinements in the conceptualization of personality that point to a multidimensional view and to a unique role for projective techniques; and (iii) improved understanding and use of the specific projective tools.

Methods and constructs in other subfields of psychology provide a hospitable *zeitgeist* for projective techniques and bode well for their future development and utility. Converging evidence appears to validate the basic tenets of the projective hypothesis. Concepts from psychodynamic formulations such as transference have been redefined in terms of contemporary psychology, demonstrating that such phenomena are not unique to one theory but can be understood in several ways (Singer & Singer, 1994). The examination of clinically relevant phenomena in light of conceptualizations of memories, schema, and scripts from various subdisciplines support the work in each subfield (e.g., Horowitz, 1991; Stein & Young, 1992). Cognitive theories of perception, memory, and learning are increasingly emphasizing the unconscious or implicit social attitudes (Uleman & Bargh, 1989). Research on construct availability and accessibility (Higgins, 1990) as well as script or schema theory also recognizes the influence of cognitive processes that occur outside of awareness. Knowledge from other areas of psychology will increasingly inform the designation of interpretive units for measuring personality with projective techniques. Recent interest in narrative methods to assess schema and social cognitions is applicable to thematic apperceptive techniques (Cramer, 1996). Stories elicited through picture stimuli, like other narrative approaches, reflect the human orientation to perceive the world as stories or myths grounded in culture and personal experience.

Conceptions of psychopathology within psychoanalytic theory are placing increasing emphasis on functions of inner psychic structures and subjective meaning systems (Atwood & Stolorow, 1984). In this context, adjustment problems arise because the structures are insufficiently developed to permit adaptive coping rather than from conflict among the structures. In an analogous manner, clinical syndromes have been related to problems in the development of person schema (Horowitz, 1991). If psychopathology is a reflection of impairment in the formation of psychic structures, then it is reasonable for assessment to be geared to the evaluation of these structures (e.g., object relations, self-system, along with associated processes such as reality testing).

Levels of impairment based on the complexity and organization of inner structures will be identified along with a description of symptomatic behaviors. Projective techniques will figure prominently in the assessment of psychological variables for the purpose of intervention planning. The continued refinement of integrative therapies (Leve, 1995; Norcross, 1986) will increase the usefulness of identifying relevant processes to be targeted and matched with optimal intervention strategies.

Understanding personality according to different styles and levels of organization of experience as they relate to functioning will rest on increasing emphasis on part whole conceptualizations. For example, with a focus on inner structures, aspects of personality such as emotions will be increasingly recognized as organizing processes that shape adaptation and problem solving (Greenberg, Rice, & Elliott, 1993). Other personality processes, such as distractibility or inattention, will also be understood in relation to how they shape the development of inner psychic structures. Future research will focus on establishing linkages between various levels of personality constructs such as the role of various traits in the development of inner strivings and the organization of meaning structures. Research will also focus on clarifying relationships between discrete measures of neuropsychological processes, such as planning, organizing, retrieval from memory, or continuous attention, and the manifestation of these processes in the performance of more complex tasks analogous to real-life situations. Inherent in the part whole conceptualization of personality is the view of development as being propelled simultaneously by biological, psychological, and social forces. Within the psychological realm, perceptions and behaviors will be increasingly understood in terms of the interplay of experience with relevant affective and cognitive processes.

A multilevel understanding of personality will permit clearer conceptualizations of the utility of different types of techniques to assess different facets of personality. One example is the distinction between measures of self-attributed and implicit motives to achieve (McClelland et al., 1989). Story-telling measures of achievement motivation (implicit) were more effective in the prediction of long term outcomes such as career success, whereas self-reports (self-attributed) were better in predicting immediate choices (Spangler, 1992). The two types of measures of achievement motivation relate to different criteria, develop through different pathways, and can be understood in terms of different levels of personality.

In training programs, the professional courses are the places where the core psychological knowledge bases are integrated. Expertise in projective techniques includes the linking of the psychological processes assessed with appropriate strategies for therapeutic interventions. The complexity of interpreting projective instruments and of understanding their implications for guiding interventions requires no less than the systematic and flexible application of prior knowledge. Therefore, projective assessment can serve as a centerpiece for integrating concepts from core areas such as physiological, affective and cognitive bases of behavior. Training should emphasize the gradual development of the professional's schema to guide practice rather than the acquisition of knowledge applied in rote fashion. Trainees' schema should be sufficiently broad and flexible not only to incorporate information currently available but to accommodate continuous learning throughout the professional career. Measures are simply tools. Rather than emphasizing the assessment technique, training programs would do well to focus on the development of integrative frameworks that include how various sources of information fit together into meaningful patterns.

Increased acceptance of qualitative measures as having scientific merit has led to more frequent use of open-ended methods in the study of personality such as the study of early memories (Bruhn, 1992), thought sampling (Rubin, 1986), examination of the life story (McAdams, 1990), self-defining memories (Moffit & Singer, 1994), and analysis of therapy transcripts (Luborsky & Crits-Christoph, 1990). The psychometric challenges of projective methods are shared among all open-ended techniques. The effort to master these difficulties will require, above all, conceptual clarity and an emphasis on construct validation. These endeavors will promote shared conceptualizations and methods across disciplines, appreciation of the progress already made with projective techniques, and the spurring of further developments.

Frameworks for interpretation of projective techniques not only elucidate the inner structure of personality but reveal problem-solving strategies in relation to the task demands. Therefore, it may be fruitful to view these techniques, in part, as *performance measures of personality* that can be compared to other tests in an assessment battery in terms of what the task requires. The most significant difference is that performance tasks of personality maximize the use of spontaneous strategies to organize perceptions and responses. Variation in response patterns across different types of tasks permits distinctions between knowledge structures that are inert and require external prompts from those that are meaningfully organized and spontaneously accessible. Furthermore, the configuration of responses within and across diverse tasks foster explanations of situational variability and consistency in performance and behavior. For instance, social situations require the individual to organize perceptions, size up intentions, and anticipate reactions of others. These requirements are similar to the demands of projective tests to organize perceptions of the stimuli and coordinate the responses with the instructions.

The relationship between content and formal elements in the units of inference drawn from projective techniques still needs to be clarified. The most fruitful approach to integrating the analysis of form and content is through the identification of their linkages with important psychological processes. Formal structural analysis should receive greater emphasis in the apperceptive methods. Generalized properties of content and features of narrative structure are more durable indices of psychological processes than isolated content. Furthermore, the analysis of the subtext or underlying structure of narratives can yield significant information about the individual's schematic organization of experience. The struggle to apply valid and reliable methods to assessment will continue. The inevitable link between theory and method necessitates the simultaneous effort to refine both. Conceptualizations developed in other subfields of psychology and lessons learned from qualitative research methods will be applied to improve the reliability, validity, and clinical utility of projective measures.

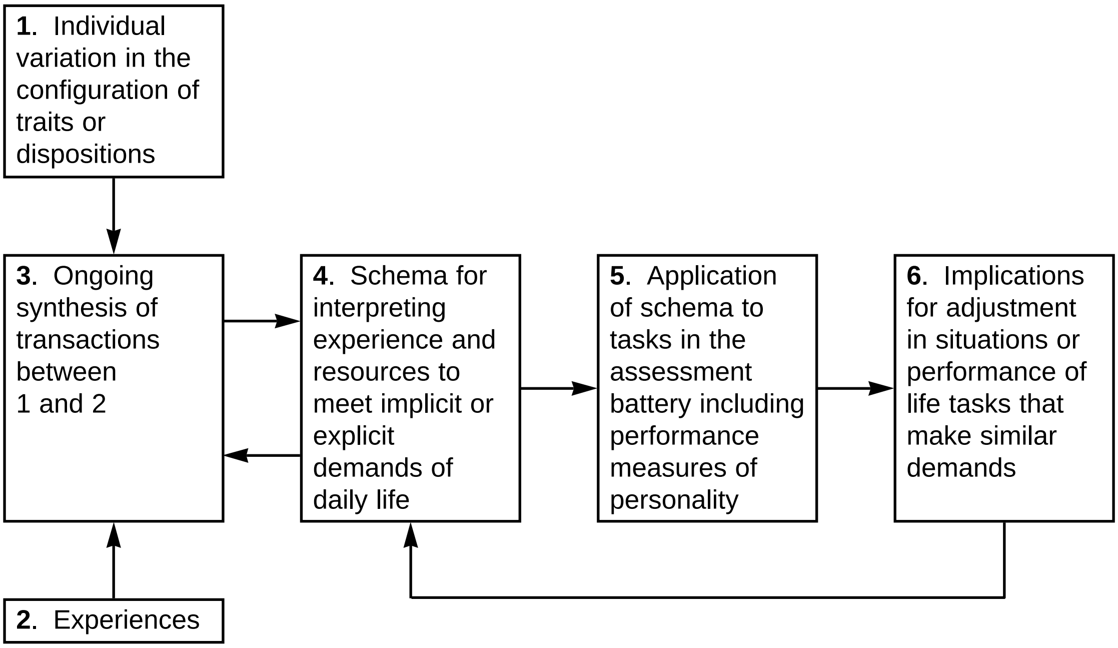
4.16.15 SUMMARY

The chapter is summarized by presenting a model for understanding performance measures of personality shown in Figure 2. The interaction of the person and environment (boxes 1 and 2) as a fundamental unit of study has wide acceptance and applicability. However, the objective features of the environment and the subjective world are not the same. Lewin (1935) refers to the psychological environment as the inner experience of external reality. Persons participate in and influence their external environments as well as being shaped by them. The manner in which the individual encodes and stores encounters with the external world drives the construction of the inner psychological world (box 3). Therefore, one can only conceptually separate the person from the environment—they are embedded in one another.

Schema are memory structures that develop through the individual's constant and reciprocal transactions with the environment. The development of schema is influenced by (all factors said to influence personality) various interactive determinants including constitutional factors of temperament (see reviews by Emde, 1989; Plomin, 1986) as well as meaning structures transmitted by family and culture in conjunction with the individual's experiences throughout life. These schema are important to assess because they: (i) are mental sets that guide attentional processes and serve as filters for interpreting information; (ii) guide actions in situations that require complex resources; and (iii) shape the storage of new information in memory.

Certain conditions such as attention-deficit hyperactivity disorder are diagnosed through a careful examination of previous history as well as scrutiny of current behavioral patterns. However, these attentional processes shape the individual's prior and ongoing synthesis of experience through their impact on the information entering awareness, the feedback received from others and on the development of internalized schema. Therefore, the part–whole relationships between specific symptoms or psychological processes and larger units of the personality need to be understood. Projective testing relies on an appreciation that overt behavior is linked to inner meaning. Consequently, inner life is a mechanism for perceiving the outer world and for regulating behavior to adapt to these perceptions. The projective techniques (e.g., TAT and Rorschach) provide information about how prior experience has been organized and how inner resources (schema, inner structures) are applied to relatively unstructured situations. Responses to projective tasks are understood as cohesive products reflecting all of the processes involved in the synthesis of experience. Specific psychological processes such as attention or emotion can be studied as precursors and sequelae of the development of inner structures.

Projective techniques require a person to demonstrate the qualities of organization and strategic planning by performing a problem-solving task rather than by telling about the self in an interview or by responding to a questionnaire. Therefore, the term *performance measure of personality* aptly describes projective methods. These performance measures are less structured than the other tasks in the typical assessment battery and provide unique information. The manner in which the problem is solved



1. Individual variation in the configuration of traits or dispositions
3. Ongoing synthesis of transactions between 1 and 2
4. Schema for interpreting experience and resources to meet implicit or explicit demands of daily life
5. Application of schema to tasks in the assessment battery including performance measures of personality
6. Implications for adjustment in situations or performance of life tasks that make similar demands
2. Experiences

Figure 2 Understanding performance measures of personality.

or the task is accomplished reveals the individual's organizational strategies and resources to deal with similarly unstructured situations. In addition, the nature and organization of knowledge structures reveal the frameworks or convictions that guide responses in ambiguous situations. Furthermore, inferences drawn from performance measures and self-reports pertain to different facets of personality and predict different criteria (McClelland et al., 1989).

As Figure 2 shows (box 4), the individual's ongoing synthesis of experience leads to the development of knowledge structures. Various performance measures in an assessment battery can be examined in terms of what the task requires and what inner structures or resources are brought to bear on the performance (box 5). Actual adjustment in a given situation (box 6) depends not only on the person's resources but also hinges on environmental expectations and supports.

The person is assessed within a particular social context of the testing situation including expectations about testing, anticipation of the potential consequences of testing, and the relationship with the examiner. Therefore, these variables are considered along with the task demands. The job of the examiner is to organize multiple sources of data including reports of self and others, various performance measures, relevant past history, and current circumstances into a framework for understanding the referral issues. All of the information is sifted through an understanding of family and cultural background as pertains to the individual being assessed. The understanding is informed not only by theories of personality, human development, and psychopathology, but also by a conceptualization of the various tasks in the battery and how they relate to performance in life situations. Findings are not a listing of isolated facts but conclusions based on cohesive patterns that provide an understanding of the problem and point to appropriate action.

4.17.1 INTRODUCTION

A common dilemma for clinical psychologists is the tension between the need for diagnosis and the complexities of the individual case. Although resources to help the client may be contingent on certain types of psychological disorders, concern for the client and the avoidance of stigmatizing labels clearly make assessment difficult when cases are unusual or complex. Also, time may be limited or resources of the client may be limited, making an extended assessment difficult to complete. In the midst of this dilemma, various methods of computer assisted psychological assessment (CAPA) have emerged and some have become prominent, especially with the advent of the personal computer in the 1980s, with both promise (e.g., Jackson, 1985) and potential problems (e.g., Matarazzo, 1986). This chapter surveys the definition, history, types of implementation, advantages and disadvantages, reliability and validity concerns, and issues of ethical and professional responsibility in the use of computers in assessment. No attempt will be made in this chapter to review or critique actual software or existing CAPA programs, except by example or reference, due to the rapidly changing nature of the technology and the continual updating of various programs. This chapter will, however, take a hard look at the proposed advantages of CAPA, and, instead of placing inordinate weight on the technical promise of computers, propose some firm limits on the use of CAPA. First, some definitions and important distinctions are made, followed by a brief history of the development of CAPA.

4.17.1.1 Definitions and Distinctions

CAPA is broadly defined as any application of computers to the development, administration, scoring or interpretation of tests, scales, inventories or questionnaires used in education or psychology.

Psychological texts such as Gregory (1996) have proposed similar definitions. Those appear consistent with early use of the term CAPA such as that employed by Fowler (1985). The present chapter will focus more narrowly on computer applications to cognitive or personality instruments in which administration, scoring, and interpretation are attempted. Methods of CAPA development and techniques of using computers in test development are beyond the scope of the present chapter. For a review of some of the technical methods proposed for the development of computer-based psychological tests, see Green (1991a) on adaptive testing; Guastello and Rieke (1994) on the expert-system approach; Snyder, Widiger, and Hoover (1990) for a review of test-interpretive program development; and the review by Roid (1986).

By "assessment" we refer to the process of examining the entire range of information, including standardized tests, scales, inventories, questionnaires, protective tests, observations, interview data, histories, and other observations by experienced psychologists who study an individual for purposes of diagnosis, description, classification, treatment planning, pre-therapy observation, or any other professional evaluation. Most psychometric textbooks make an important distinction between assessment and "testing" or "measurement." Testing usually involves the administration of standardized stimuli (e.g., test or inventory items) to clients whose responses are scored by objective or judgment-based scoring methods. Measurement is traditionally defined as the assignment of categories or scale values to such aspects of individuals as traits, attributes, attitudes, behavior, and preferences by a psychological testing instrument. The word "test" is typically reserved for tasks in which there are correct answers or problems to be solved, in contrast to "scale" or "inventory" or "questionnaire" which measure traits or preferences for which no single correct answer exists for all people.

Matarazzo (1986) made the most vivid distinction between testing and assessment by arguing that assessment should be reserved as a term to describe the process conducted by an experienced psychologist who gathers information for purposes of interpreting it and giving it meaning within the context of the examinee's total life history. Matarazzo's distinction would result in questions such as, "Can computers really provide assessments or only measurements which must be interpreted by professionals?" This penetrating question strikes at the heart of the ethical issues to be discussed in this chapter. Matarazzo was contrasting his definition of assessment with the technical, clerical, or computerized processing of test information. His position received immediate reactions such as that of Fowler and Butcher (1986) who argued for the view of the assessment process as one that could include both clinical and computerized statistical assistance in the interpretive process.

The standards for psychological testing (American Psychological Association (APA), 1985) make a distinction between test administration and test interpretation, and warn that test developers should inform users of any special training or expertise needed for either administration or interpretation. Thus, CAPA may be used for test administration, for administration and scoring, or for a full range of administration and interpretation. Typically, a higher level of training is assumed for the interpretation of test results, such as graduate-level measurement or psychometrics courses, supervised assessment and reporting, and knowledge of concepts such as error of measurement. Also, a higher level of validation is required for any interpretations of tests that impact clients. The distinction between administration and interpretation of tests is critical to the evaluation of CAPA and the role of computers because it highlights the continuing responsibility of the psychologist to proactively interpret the results of the assessment process. Thus, we define another category of programs, computer-based test interpretive (CBTI) programs, to delineate those that emphasize interpretation, often with narrative descriptions of results.

A final distinction of great importance was first discussed in depth by Meehl (1954) —clinical versus statistical (actuarial) prediction. By clinical prediction, common usage would normally suggest the processing of information by the trained clinician who makes a prediction, diagnosis, classification, or evaluation of a client based on clinical experience, "intuition," and professional judgment. By statistical prediction, common usage would suggest methods such as multiple regression or validated "cutting scores" being used to predict, diagnose, and classify an individual based on a relevant research database. Meehl's (1954) lengthy discussion of the issues pointed out important distinctions such as the fact that both clinical judgment and statistical methods may be predicting an individual case from trends in previous group data—the group of all previous clients in the instance of clinical judgment. Later researchers such as Goldberg (1968) showed that clinical judgments are not necessarily more complex or "configural" as compared to statistical predictions, since simple linear equations effectively modeled the behavior of skilled judges who were assessing, for example, psychosis vs. neurosis from the Minnesota Multiphasic Personality Inventory (MMPI). It would be impossible to summarize all of the careful distinctions among clinical vs. statistical methods, and the reader is referred to Meehl (1954), Goldberg (1968), or to the review by Garb (1994).

4.17.1.2 Brief History of Computer Assisted Psychological Assessment

Fowler (1985) and Moreland (1992) provide brief histories of CAPA. Highlights include the early attempts in the 1940s to computer score the Strong Vocational Interest Blank (SVIB), Meehl's (1954) landmark book, and early 1960s versions of mainframe computer programs to score and interpret MMPI responses. To say that the history of CAPA has followed the development of computers and scanning equipment is obvious, but several landmarks are instructive. Following the refinement of mainframe computers in World War II, and until approximately 1970, most efforts to study or implement CAPA were conducted on mainframe computers with several critical attributes: (i) access to the computer was typically limited to professional computer operators, (ii) programs were developed and operated in "batch" mode where little interaction occurred between the user and the computer—interactions were specified in advance with various control commands, and (iii) the responses of examinees had to be scanned by a separate document scanner or key entered. Thus, "dynamic" entry of data was not possible at most installations. The advanced development of high-capacity scanning equipment is often attributed to Lindquist and his colleagues at the University of Iowa (e.g., Flanagan & Lindquist, 1951), for use on various educational achievement tests, although similar developments were employed for the SVIB and the MMPI (Moreland, 1992).

In the 1970s (and, perhaps, earlier in experimental laboratories), "time sharing" computer systems proliferated that connected the user via Teletype machine or early versions of computer terminals. Some CAPA applications were developed on systems initially designed for computer-assisted instruction. These "real time" systems allowed for a degree of interaction between the programmer and the system, between the user and the output, and, in some experimental applications, between the examinee and the time-share computer (e.g., Klingler, Miller, Johnson, & Williams, 1977). Klingler et al. developed an automated assessment system for psychiatric inpatients at a veterans administration hospital in Utah. The potential cost-benefit of such applications was immediately apparent, and this stimulated discussions at psychological conventions about the ethical issues of on-line test administration and scoring.

Another important innovation in CAPA was the development of multistage "branching" or "adaptive" tests, which emerged from early psychometric studies in educational measurement (e.g., Angoff & Huddleston, 1958; Linn, Rock, & Cleary, 1969; Lord, 1968, 1971), from sequential methods in statistics (e.g., Cowden, 1946; Wald, 1947), and from the development of item-response theory (e.g., Birnbaum, 1968; Rasch, 1980). As early as the late 1960s, there was a considerable unpublished literature on adaptive testing methods and their application to psychological scales as well as educational tests (e.g., Bayroff & Sealy, 1967; Patterson, 1962; Roid, 1969). However, the first widely distributed applications of computerized adaptive testing emerged in the 1980s. Weiss (1983) was a key developer of methodology and applications in college and military settings. Operational programs on personal computers emerged in aptitude testing (e.g. McBride, 1988) and in conjunction with a large-scale project to computerize the Armed Services Vocational Aptitude Battery (ASVAB; Green, 1991a; Sands & Gade, 1983).

With the development of the first Apple computers and the release of the first IBM personal computer in approximately 1980, the widespread implementation and practicality of CAPA for the local psychologist was finally available. The early 1980s witnessed a flurry of rapid development and distribution of test scoring and interpretive programs for microcomputers (e.g., Roid & Gorsuch, 1984). In reaction to the swift proliferation of CAPA programs, Matarazzo (1983) published a stern warning about the lack of validation of narrative interpretations and the potential dangers of distribution to inexperienced users. Special series of articles appeared in the *Journal of Consulting and Clinical Psychology* (Butcher, 1985), and *Computers in Human Behavior* (Mitchell & Kramer, 1985.) These early articles were a mixture of praise about the potential of the methodology and warnings about the limitations and ethical consequences of irresponsible usage. In response to this outpouring of attention to CAPA, the APA (1986) published a booklet of guidelines for development and usage of "computer-based tests and interpretations" (see Table 2). Several resource books, cataloging various programs and user options, were published (e.g., Butcher, 1987; Krug, 1984).

Because of the rapid innovation in computer technology, and, in the mid-1990s, the development of the world-wide web, Internet, video conferencing, and multimedia desk-top computers, it is difficult to anticipate the developments in CAPA. Certainly, the addition of multimedia to assessment instruments will be more easily achieved and affordable by more test developers. Dynamic video segments within standardized tests could make real-life situational assessment more feasible. In any case, the potential and the new ethical concerns stimulated by the prospect of test processing by Internet or e-mail services looms large on the horizon.

In the next section, we review a typology of CAPA programs. Included is a review of some of the key literature that documents the current status of CAPA and further definitions and distinctions.

4.17.2 A TYPOLOGY OF COMPUTER ASSISTED PSYCHOLOGICAL ASSESSMENTS

Not all applications of CAPA have the same level of complexity or developmental sophistication to support them. Thus, it is important to have a typology of various programs so that the proper role of CAPA can be evaluated. It will be the overall recommendation of this chapter that the psychologist carefully evaluate the level and type of CAPA product considered for clinical use, and perhaps, "draw a line" of restriction in terms of the type, technical quality, and validity of CAPA results actually employed in the evaluation of clients. For these reasons, a typology of CAPA programs, derived from the literature and the previous work of the senior author (Roid & Gorsuch, 1984; Roid, 1986), is presented below. First, a few key distinctions and definitions are discussed.

As stated earlier in this chapter, a wide range of computer "assistance" is used in the development of psychological tests and assessments, and we have chosen to delete these programs from our typology in favor of emphasis on CAPA products that may be directly used in client assessments. Also, there are a potentially large number of CAPA products available in the "employment testing" industry that are not considered due to the clinical focus of the current discussion. Finally, computer-based products that are designed for on-line delivery of psychotherapeutic exercises or cognitive training are excluded, even though some of them include assessment components.

Significant differences exist between CAPA programs for cognitive, neuropsychological, and personality assessments. Some of the same statistical techniques have been applied to the profile scores of both ability and personality batteries, but, for the most part, each has a particular type and style of presentation. For example, it is now common in the software to score intelligence scales to include computations, frequencies, and probabilities of differences between two or more subtests or indexes (e.g., verbal IQ vs. performance IQ). Statistical contrasts of differences are more rare in personality assessment, where, instead, visual inspection of the profile of scores is more common. In computerized interpretive programs in the personality realm (e.g., Lachar, 1984), it is common to include "critical items" and correlates between clinician ratings and "profile elevations" (ranges of scores, such as 70–79T on the MMPI). However, in terms of the typology that follows, the collective statistical techniques can be classified together as "profile and statistical analysis."

Table 1 A typology of computer assisted assessment.

- *Test administration*
  - Conventional test administration
  - Multimedia or specialized test administration
  - Computerized adaptive testing (CAT)
- *Computer scoring*
  - Conventional scoring
  - Statistical scoring and profile analysis
  - Graphic displays
  - Database analysis
- *Descriptive interpretation*
- *Narrative interpretation (CBTI programs)*
  - Informal narrative
  - Clinician-modeled or expert system
- *Statistical–Actuarial interpretation*

4.17.2.1 Test Administration

Table 1 presents the typology. Some software is designed to administer tests and to record the results, which may be printed or briefly summarized on the computer screen. Administration can include highly sophisticated, multimedia programs with attached database capability, such as the MicroCog by Powell et al. (1993), an on-line testing system to detect cognitive impairment in older adults. Programs can vary from basic "page turning" software that simulates paper-and-pencil tests, to those such as MicroCog that include graphic displays, reaction time, optional sound, and delayed memory trials also timed. Of particular importance in this category of the typology, are programs such as the Conners' (1995) Continuous Performance Test (CPT), used to assess attentiveness, particularly for children and adults referred for attention-deficit evaluation. The CPT assesses visual vigilance in scanning and concentrating on a stimulus array—a type of performance that must have accurate, split-second timing of both stimuli and responses—a perfect application of computers in test administration.

A separate category of test administration is computer-adaptive testing (CAT). CAT requires specialized software to implement the sophisticated (usually item-response theory or Bayesian) statistical model on which it is based. Several prominent examples exist, including the newer versions of the computerized Graduate Record Exams (Educational Testing Service, 1995), the ASVAB (Sands & Gade, 1983), and, one of the first widely published commercially published tests, the Differential Aptitude Tests (DAT Adaptive) Computerized Adaptive Edition (Psychological Corporation, 1987). The essential attribute of CAT administration is that the difficulty of the test items is tailored dynamically (Lord, 1968) to the ability level of the examinee during the testing session. Research (e.g., Green, 1991a) has shown that modern implementations of CAT can reduce testing time by half while maintaining an acceptable level of measurement error. To implement such a system requires complex psychometric development in which each item in the pool of available items is given field trials and calibrated statistically. Programs such as MicroCAT (Assessment Systems, 1990) or other specialized computer programs are then used to implement the presentation of items. A broad range of "branching rules" and scoring methods are now available for such tests, depending on the type of item-response theory model used in the calibration of the items (e.g., Wainer, 1990).

While the statistical complexity of CAT applications may be beyond the level of psychometric training for many clinical psychologists, one can consult the professional reviews of such tests in the *Buros Mental Measurements Yearbooks*, or the current on-line electronic versions of these reviews. Alternatively, legitimate CAT programs should have an accompanying manual which can be evaluated for conventional reliability and validity data, just as any published test is evaluated. Psychological conventions and meetings often include exhibits or demonstrations of computer software, which can be a more cost-effective way to review these products, since publishers are often reluctant to distribute expensive software for review. As a final recourse, one should consult a psychometric psychologist at a local university who can help to evaluate the technical qualities of programs considered for purchase.

4.17.2.2 Computer Scoring

Conventional scoring software has typically processed answer sheets or key-entered item responses and printed basic raw scores and various derived scores such as percentiles or standard scores. For many years, such programs had a minimum of graphic display, due to the restricted nature of graphics possible until the advent of the high-speed laser printer. As mentioned in the brief history of CAPA, the earliest versions of conventional scoring were on mainframe computers for the SVIB or the MMPI. Many of these programs were quite creative and complex, relying on "typeface" characters to plot profiles or display histogram-type plots of scores.

At the next level in the typology are scoring programs that include sophisticated statistical computations and profile analysis. A proliferation of "scoring assistant" programs has emerged, such as the "compuscore" series for the Stanford-Binet and Woodcock-Johnson at Riverside Publishers, the PsyTest and Wechsler Intelligence Scale for Children-Third Edition (WISC-III) and Wechsler Individual Achievement Test (WIAT) programs of The Psychological Corporation, the Western Psychological Services Test Report series, the software systems developed by Psychological Assessment Resources, and the "Assist" software for the tests published by American Guidance Service, to name a few of the larger groupings of scoring programs. Although many of these programs also include interpretive functions, to be discussed in the next section, the scoring sections of these programs tend to be more graphic and more sophisticated than earlier, conventional scoring programs (Roid, 1985). For example, a much wider array of profile indexes, score-difference analyses, critical item comparisons, and profile-matching routines are included than previously available programs (with exceptions being some of the complex, early MMPI interpretive programs). Two examples, one in personality and one in cognitive assessment, may illustrate the characteristics of such programs. The Tennessee Self Concept Scale (Roid & Fitts, 1988) computerized scoring program includes a wide array of research-based profile indexes, checks on the validity of response patterns, faking-good scales, critical-item lists, and a multivariate profile matching method that is implemented on a complex, color-printed display. The profile-matching method, interval-banded profile analysis, was initially developed by Huba (1986) to provide a statistical test of the degree of match between prototypical profiles (stored within the computer program) and those of new profiles being scored. The essential part of the matching routine is a multivariate chi-square test of "fit" between the profile pattern (which is allowed to vary within "bands" or ranges of scores) and "target" prototypical patterns that have been established through statistical studies of clinical and normative cases. A second example of sophisticated profile analysis is in the Wechsler Scoring Assistant (Psychological Corporation, 1992), where profile-score differences among all the subtests of the WISC-III are analyzed statistically, and the regression–prediction method of calculating ability vs. achievement discrepancies (WISC-III vs. Wechsler Individual Achievement Test scores) are included for screening of learning disabilities.

As more and more technical advances are made in computer printers, compact-disk and computerized video displays, the more sophisticated the graphic display of test profiles and score patterns will become. In the final level of the typology are programs that allow for the archiving of multiple cases, set up and usage of extensive databases of test results, and statistical manipulation of these data. Examples of such programs are found among the offerings of all the publishers of the large achievement-test batteries, who typically offer software for analyzing trends in achievement data across an entire school district. The most sophisticated versions of these programs allow for the assessment of growth or change at the individual, classroom, and school levels of analysis.

Based on the experience of the senior author of this chapter, who participated in the development of several computer-scoring systems (e.g., Roid, 1985; Roid & Fitts, 1988; and the Wechsler Scoring Assistant, Psychological Corporation, 1992), these profile-analysis programs are typically based on extensive data analysis, not informal or subjective processes that often occur in the "informal narrative" category of the typology. Most of the profile analyses are based on actual data from the standardization and validity studies of the major tests, and extensive staff, resources and time are invested in the development, and (elaborate) cross-checking of program accuracies. Because it is well known that clerical errors in scoring standardized tests are all too common, these scoring programs provide a valuable service to clinical psychology by delivering accurate scores. Further, the complexity of profile analysis, difference-score computation and analysis, and profile-pattern matching would not be feasible with hand-scoring methods. Except for a few unusual cases, the statistical scoring programs tend to be well documented in the technical manuals published with them.

Thus, in summary, the sophisticated "scoring assistant" model of computer scoring software has distinct advantages for the clinical psychologist. Time saved by the clinician in using scoring software could be reinvested in more time with the client or additional personal interview or case follow-up.

4.17.2.3 Descriptive Interpretation

A descriptive type of program would generate sentences of explanation, such as "The client has a significantly higher score on subtest three as compared to the other subtests in the profile," along with the printed scores and profile. The distinction between this level of description and the narrative interpretations described in the next section of the typology is that description remains tied to the facts and does not indicate cause-effect relationships or connections with research or clinical findings. The descriptions would be analogous to the phrases used in the results section of a research article—reporting the findings before they are discussed or interpreted. As noted in the example above, the descriptions can be rooted in sophisticated statistical comparisons between scores (e.g., Silverstein, 1981).

Some of the first computer interpretive programs widely used in the 1980s had redundant, printed phrases that described score elevations for multiple scores, using exactly the same wording. The best examples of descriptive interpretation include sophisticated "sentence generators" that compose explanations using a variety of modifiers, sentence construction and style, similar to the variety present in good report writing. One example is that of the Barclay Classroom Assessment System (Barclay, 1983) which varied pronouns such as "he" and "she," and used research on the scaling of verbal phrases (e.g., Lichtenstein & Newman, 1967; Pohl, 1981) to compose explanations of score elevations. For example, scale values for descriptors such as "fairly often" vs. "very infrequently" can be used to anchor score-level descriptions, in a way more precise than an informal or subjective use of such language. Use of more precise methods of description, could increase the potential of such programs to maintain a more objective level of description, that is, sticking to the facts.

4.17.2.4 Narrative Interpretation

The worst examples of informal, unvalidated, narrative interpretations of psychological tests were the target of Matarazzo (1983, 1986) in his critiques of CAPA. By informal narrative we mean the wordy descriptions printed on computer reports of assessment results that attach clinical significance, often based on clinical lore or theoretical explanations, to the patterns or levels of scores. Such narratives have been faulted for lack of validation of specific sentences or phrases and for lack of attention to individual client variations. Informal narratives also have the impact of vague generalities that result in a "Barnum effect" in which enough truth lies within a complex of statements if one emphasizes the accurate parts and minimizes the inaccurate parts. In research on the accuracy of computerized reports, Adams and Shore (1976) found an inverse relationship between length of reports and their accuracy rated by clinicians. For these reasons, clinicians should be very cautious about the validity of informal narrative programs.

Basically, the key feature of such programs, that clinicians should be able to discern from the manual and advertising material published with the computer program, is whether or not the narrative sentences have been accumulated from empirical research or whether they were written by the author(s) of the program without validation studies. Another key is whether or not the statements were validated by empirical linking of clinician ratings and scores, where both were collected in the same research studies. Positive examples of proper validation of narrative programs are reviewed by Snyder et al. (1990). Published programs that include extensive empirical validation of narrative reports include Lachar (1984) and Snyder (1981), to name only two prominent examples.

By clinician-modeled programs we mean those that either (i) employ the process used by a renowned clinician within the logic of the computer program, or (ii) employ statistical models of the process used by expert clinicians, determined through research on clinical judgment (e.g., the methods described by Goldberg, 1968). Examples of the former include the WISC-III program of Kaufman (1996) that implements his documented approach to interpretation of the Weschler scales (Kaufman, 1994). Examples of the latter have never been implemented, as far as we know, although the methodology is particularly promising. For a review of expert systems and their application to CAPA, see Guastello and Rieke (1994).

4.17.2.5 Statistical–Actuarial Programs

The term "actuarial" as applied to psychological assessment was coined by Meehl (1954) in analogy to the actuary process in insurance-risk determination. Gregory (1996) presented a classic definition of an actuarial interpretation, attributed to J. O. Sines, as founded on "the empirical determination of the regularities that may exist between specified psychological test data and equally clearly specified socially, clinically, or theoretically significant nontest characteristics of the person tested" (p. 579) Thus, an actuarial approach is databased and must show a statistical link between information collected outside the test (e.g., clinician's observations) and the test scores or patterns of test results. At their best, narrative statements appearing in a truly actuarial program would not be based on clinical opinion, but rather on rigorous research linking test and nontest information.

A classic example of an actuarial approach to the MMPI is provided by Marks and Seeman (1963) who defined a 4–8–2 profile "code type" as follows:

(i) Scales 4, 8, and 2 over 70T
(ii) Scale 4 minus 2 less than 15T
(iii) Scale 7 not to exceed 4 by more than 4T
(iv) Scale 8 minus 2 less than 15T
(v) Scale 8 minus 7 more than 5T
(vi) Scale 8 minus 9 more than 10T
(vii) Scale 9 less than 70T
(viii) Scales L and K less than F, F less than 80T

Thus, detailed specifications are given for the entire profile pattern, not just the high scores on 4 (psychopathic deviate), 8 (schizophrenia), and 2 (depression). Even the validity scales, L (lie scale), F (frequency), and the suppressor scale K, are used to verify the accuracy of the profile. Marks and Seeman (1963) reported that patients obtaining this profile were mainly diagnosed psychotic (71% schizophrenic, paranoid type) though some were seen as personality disorders (e.g., 21% sociopathic). Note that these are percentages for a given sample of clinical patients, and that they do not predict with 100% accuracy, as with all probability relationships. Therefore, the most accurate statement that should appear in narrative form would be something like, "some research studies of clinical patients have shown a frequency of about 70% schizophrenic–paranoid for this pattern of scores," and the clinician should be careful to screen all such comments to be sure they apply to the current case.

Another type of actuarial approach called "empirical correlates" was developed by Lachar (1984) for the Personality Inventory for Children (PIC) computer interpretations. Lachar administered clinical checklists to psychologists who had interviewed children who were subsequently tested with the PIC and, previously, known to have certain diagnoses. In addition, a large sample of children in a normative sample were given the PIC and the checklist was completed by examiners for these children also. For certain scales (and certain scale elevations, e.g., scores greater than 79T), empirical correlates were those descriptive statements statistically associated with the "elevation" (score in the clinical range). For example, for the achievement scale, a percentage (e.g., 73%) of clinical cases would show symptoms such as behavioral adjustment difficulties or negative self concept (as indicated on the clinical checklist), when the achievement scale score exceeded 79T. To confirm such findings, the same correlational study would be repeated as a cross-validation. Since empirical findings always "shrink" upon cross validation, the percentage may reduce to 70% of cases in the above example.

The best statistical–actuarial interpretation programs are those that meet the standards suggested by Snyder et al. (1990), where cut-score rules, program logic, and narrative sentences have been subjected to empirical research and are well documented in a technical manual. Also, the best of such programs have been subjected to validation research that surveys clinical users of the reports, collects accuracy ratings, and assesses the impact on clinical decisions of various client reports in rigorous follow-up studies. The number of programs with such rigorous development are, unfortunately, few. Some systems that come close are the larger, well-researched MMPI programs, the PIC (Lachar, 1984), the Marital Satisfaction Inventory (Snyder, 1981), and the Wechsler programs developed by the Psychological Corporation (1994), to name only four examples. Even these programs can be faulted in that every phrase or descriptor may not have been subjected to empirical trials based on moderator variables, and all may not have been examined for report accuracy. Such research, as with all good construct validation, takes decades of accumulated research. One trend and positive aspect of some of the newer programs (e.g., WISC-III Writer, Psychological Corporation, 1994), is the provision for placing the clinician in control of the final collection of narrative statements that appear in the report. As will be discussed in later sections of this chapter, the individual clinician must maintain control and oversight over the selection and accuracy of all statements generated by computer interpretations that are employed in case reports.

With the typology of CAPA programs in mind, the following section reviews some of the advantages and disadvantages of CAPA. Key literature is cited in the next section.

4.17.3 COMPUTER ASSISTED PSYCHOLOGICAL ASSESSMENT: ADVANTAGES

Computerized approaches to psychological assessment have rapidly become standard practice in most mental health treatment settings. Not only have computer administration and scoring of various tests become commonplace, but CBTIs have become a booming industry in their own right. In 1989, a survey of 413 mental health facilities in the USA revealed that 53% of these major facilities employed some form of CBTI (Piotrowski & Keller, 1989) CAPA offers numerous advantages to users, organizations, and clients alike. The following are some of the more salient advantages.

4.17.3.1 Improved Administration and Scoring

Computer administration of psychological tests serves to enhance standardization and clinician control over the testing process. In addition to reduced time for administration and rapid availability of feedback, computer administration allows presentation of even complex testing stimuli (Krug, 1987) and early identification of examinees who misunderstand directions or test stimuli (Wise & Plake, 1990). Though some have expressed concerns about the equivalence of computer administered test scores, reviews suggest that when instructions are similar, computer-administered tests generally yield scores which are equivalent to paper and pencil versions (Finn & Butcher, 1991). Additionally, preliminary research indicates that computer-administered tests are not only acceptable to examinees but often preferred over conventional testing procedures (Burke & Normand, 1987; Finn & Butcher, 1991). Specifically, examinees report greater interest, less anxiety, and greater comfort in responding to computer generated test stimuli. Computer-administered tests are also quite useful for more disturbed clinical populations who, by virtue of their level of disorganization or inattention, may respond more effectively to a computer than another person (Bloom, 1992).

4.17.3.2 Objectivity

In his early call for a good actuarial "cookbook" for use in psychological assessment, Meehl (1956) noted the potential benefit of decreased distortion and bias, in the recording, storage, and retrieval of test data and interpretive material. Most appear to agree that CAPA can substantially reduce errors associated with ignorance, bias, or stereotyping on the part of clinicians (Butcher, 1987; Dahlstrom, 1993). Once interpretive rules are developed and programmed, they are automatically applied to protocols regardless of extraneous circumstances.

4.17.3.3 Speed

Perhaps the most pragmatic and obvious advantages of computer assisted psychological assessment is the potential for marked reduction in time required for administration, scoring and interpretation of psychological instruments (Butcher, 1987; Kleinmuntz, 1969, 1975; Wise & Plake, 1990). Administration time for both achievement and personality tests is significantly reduced by computer administration (Wise & Plake, 1990). Computerized scoring and interpretive report generation serve to enhance timely processing of test data by clinicians and subsequent delivery of feedback to consumers. In addition, these substantial reductions in time are associated with improvements both in consistency and accuracy.

4.17.3.4 Reliability

Computer assisted scoring and interpretation of psychological tests serves to radically reduce error variance. Butcher (1987) noted "The computer seldom has an off day as human test interpreters do" (p. 5). As a result, well developed test interpretation programs offer nearly perfect reliability for the functions of scoring and compiling preprogrammed interpretive statements (Burke & Normand, 1987; Graham, 1993; Krug, 1987). Once scale correlates have been identified and replicated, they can easily be stored and reliably recalled when particular scale elevations or score configurations appear in a protocol.

4.17.3.5 Cost Effectiveness

Computer scoring and interpretation of psychological tests generally result in marked reduction in clinician time and, therefore, expense to the consumer (Burke & Normand, 1987; Butcher, 1987; Graham, 1993). Though computerized systems will certainly require an initial outlay for equipment, software, and training, long-term savings to both users and consumers may be expected. With the advent of managed behavioral healthcare and increasing attention to issues such as cost-effectiveness, efficiency, and treatment utility, CAPA offers several ways for clinicians to reduce the time and expense required for a thorough assessment.

4.17.3.6 Expert Consultation

Many modern day CBTI programs appear to have effectively realized Meehl's (1956) hope for systems which employ large databases and widely representative samples on which to base predictions and diagnoses. Many well developed CBTIs systematically organize and access massive normative databases and extensive bodies of empirical research findings to bolster and undergird test interpretations (Krug, 1987). In spite of some methodological weaknesses, research on the equivalency of computer generated vs. clinician generated test interpretation suggests many CBTIs perform at least as well as clinicians (Bloom, 1992; Burke & Normand, 1987; Finn & Butcher, 1991). For example, Kleinmuntz (1969), in a large scale multi-site study, found that computer generated MMPI interpretations performed as well as expert MMPI interpreters and surpassed the performance of average clinicians in predicting a client's primary clinical problem.

Computer generated interpretations may ideally offer the skilled clinician a source of expert consultation. Due to the voluminous information available via the computer system, interpretations generated by a CBTI may markedly enhance both the accuracy and comprehensiveness of clinical decision making, treatment planning, and feedback to the client. Garb (1994) pointed out that even when a CBTI report appears to conflict with interview, historical, and observational data, the report can still be quite valuable in leading the clinician to consider alternative hypotheses and collect additional data. CBTIs may be most helpful when a case is ambiguous and the diagnosis unclear. Also, as a result of the "expert" and "objective" look and sound of computerized psychological reports, CBTIs may be particularly advantageous in forensic settings (Butcher, 1987) where such reports may be viewed as a form of outside and corroborating opinion. Finally, computer generated reports are particularly advantageous as a source of objective and expert opinion in the psychotherapy enterprise (Finn & Butcher, 1991). Here the test interpretive report is presented as a consultation by an outside expert and introduced for the purpose of clarification and discussion.

4.17.3.7 Flexibility

A final advantage of computer assisted psychological assessment is the flexibility possible in such systems (Graham, 1993; Kleinmuntz, 1975). Perhaps the most tangible example of this flexibility is the development and ongoing refinement of adaptive or tailored testing programs. Here the system is programmed to adjust the difficulty level or volume of material in discrete areas to an individual examinee. Examples include research with the ASVAB and the MMPI. Sympson, Weiss, and Ree (1982) found that an adaptive version of the ASVAB produced validity coefficients which were equivalent to conventional administration of the test in spite of the fact that the adaptive versions were typically one-half the length of their conventional counterparts. Similarly, Roper, Ben-Porath, and Butcher (1991) found that among 155 college age subjects, an adaptive version of the MMPI-2 (averaging 28% shorter in length) produced profiles which were equivalent to conventional MMPI-2 administration.

4.17.4 COMPUTER ASSISTED PSYCHOLOGICAL ASSESSMENT: DISADVANTAGES

In addition to the many advantages inherent in CAPA, there are also concerns and unresolved dilemmas in the development, implementation, and utilization of computerized systems. Below, are highlighted several of these potential disadvantages. These include the problem of excessive generality, scanty validity, potential for depersonalizing the assessment process, potential for misuse or client harm, and the danger inherent in viewing the computer as a competent clinician.

4.17.4.1 Excessive Generality: The Barnum Effect

Computer generated testing interpretive reports have been criticized soundly for their frequently broad and highly generalized narrative statements (Butcher, 1987; Groth-Marnat & Schumaker, 1989; Matarazzo, 1986). Butcher described this as the problem of excessive generality, otherwise known as the Barnum effect or the Aunt Fanny report. CBTIs are notorious for offering patient descriptions based on insufficient empirical research. These narrative statements then apply to most human beings and are merely modal statements vs. person-specific descriptors.

This problem appears to have consistent empirical demonstration. O'Dell (1972) found that subjects perceived Barnum reports to be more accurate descriptions of their own personality than actual computer generated interpretations of their MMPI profiles. O'Dell concluded that statements with very high base rates tend to be believed or concurred with. Guastello, Guastello, and Craft (1989) found that 58% of respondents rated Barnum reports for the Personality Profile Compatibility Questionnaire as quite accurate descriptions. Nonetheless, actual CBTI reports for this measure were rated as significantly more accurate than the Barnum reports. Less encouraging was a similar study employing a CBTI for the Exner Rorschach system. Prince and Guastello (1990) reported that the Exner report offered only 5% discriminating power for any one patient when compared with bogus Exner interpretive reports. Perhaps more concerning was the finding that approximately 60% of the CBTI statements contained statements which merely described characteristics of the outpatient population in general. Related to this concern regarding Barnum statements and excessive generality is the frequently expressed concern regarding an "aura" of credibility or accuracy potentially attributed to CBTI reports by consumers. The scanty research in this area suggests that this concern may be largely unfounded and consumers rate the quality, credibility, and accuracy of CBTI or clinician generated reports as essentially similar (Andrews & Gutkin, 1991).

4.17.4.2 Lack of Validity

One of the most glaring problems inherent in the development and use of CBTI report systems is the pervasive dearth of empirical evidence of their validity. Very few of the existing CBTI systems have been validated in even a rudimentary manner (Butcher, 1987; Finn & Butcher, 1991; Matarazzo, 1986). Rather than actuarial programs based exclusively on empirically derived base rate data, most CBTI reports are based on clinical lore or the conclusions and hypotheses of expert clinicians (Gregory, 1996; Groth-Marnat & Schumaker, 1989). Concerns regarding validity are often expressed as part of a larger concern about the wide range in product quality within the CBTI market. Butcher (1987) wondered at the "mind-boggling" (p. 6) array of computers and software packages from which clinicians might choose. While some systems are based on reasonably rigorous development procedures, most are not. As a result, many psychologists remain quite skeptical of CBTI programs (Burke & Normand, 1987) and avoid using them.

4.17.4.3 Depersonalizing the Assessment Process

Critics of computerized assessment systems often express concern that introduction of computers in the assessment process will serve to heighten the distance between the clinician and client and lead to a more sterile and perhaps dehumanizing assessment process (Burke & Normand, 1987; Krug, 1987). In fact, research does not substantiate this concern and instead, suggests quite the opposite. Most people appear to prefer computer administered tests and some are more truthful in response to computer administered questions (Fowler, 1985). Computer administered assessments appear particularly useful for more disturbed or anxious clients.

4.17.4.4 Potential for Misuse and Client Harm

Later in this chapter we will address a range of potential ethical problems inherent in the use of computer assisted assessment. The potential for misuse of CBTIs and resulting harm to clients is substantial and results from difficulties with their current use (Butcher, 1987; Groth-Marnat & Schumaker, 1989). First, because CBTI programs and services are widely available and sold to a wide range of professionals, it is likely that professionals without adequate awareness of the limitations of CBTIs will apply them to clients regardless of context or important mitigating factors. A related concern involves the potential for factors indigenous to computerized assessment, but irrelevant to the purposes of the test, to significantly alter test performance (Moreland; 1985). Second there may be a tendency for consumers to uncritically accept statements generated by a computer as more factual than those generated by a clinician. Finally, because CBTI reports are rarely signed, there are serious concerns regarding professional responsibility and legal culpability (Gregory, 1996). Without a qualified psychologist assuming responsibility for the service offered, potential for misuse is enhanced.

4.17.4.5 Computer as Clinician

The final potential disadvantage in employment of computers in the assessment process has to do with the danger that well trained psychologists might lose control (Krug, 1987) of the assessment process. Specifically, this would be a loss to mechanization, technology, and large marketing interests. Though clinicians clearly stand to benefit from the speed and reliability of computer driven assessments, there is concern that the expert clinician of the past will become the testing technician of the future (Butcher, 1987; Butcher, Keller, & Bacon, 1985; Groth-Marnat & Schumaker, 1989; Matarazzo, 1990). As as result of the highly professional appearance of many CBTI reports, both users and recipients of computerized narratives may confuse them with comprehensive assessments. To the extent that the skills of the human clinician are relegated to a position of diminished importance in generating assessment outcomes, and to the extent that clinicians perceive themselves as less responsible for these outcomes, there certainly exists greater risk to the profession and the consumer.

4.17.5 ETHICAL ISSUES

In light of the rapid proliferation of CAPA techniques, and CBTIs in particular, it is not surprising that this burgeoning area of research and practice has become the focus of a wide range of ethical concerns. The APA's Ethical Principles and Code of Conduct (APA, 1992) has as its primary goal "the welfare and protection of the individuals and groups with whom psychologists work" (p. 1599). Principle C from the APA code is perhaps most relevant to the ethical issues inherent in computerized assessment, "Psychologists uphold professional standards of conduct, clarify their professional roles and obligations, accept appropriate responsibility for their behavior and adapt their methods to the needs of different populations" (p. 1599). With these goals in view, we will consider several of the most salient ethical obligations for psychologists involved in CAPA. If neglected, each could serve as a source of potential harm to consumers of computerized services.

4.17.5.1 Test Development

The Ethics Code (APA, 1992) states clearly that psychologists involved in the development and provision of computerized assessment services accurately describe the purpose, development procedures, norms, validity, reliability, and applications of the service as well as particular qualifications or skills required for their use. Psychologists participating in such product development should attempt to clearly link interpretive statements to specific client scores or profiles, qualify narrative statements to minimize the potential for misinterpretation and perhaps provide some form of warning statement to alert users to the potential for misinterpretation (Hofer & Green, 1985). At the very least, the developer might note that the clinical interpretations offered in narrative printouts are not to serve as the sole basis on which important clinical decisions are made (Matarazzo, 1986). Adherence to the highest standard of the profession would also require developers to provide rather detailed information regarding the system's development and structure in a separate manual. Because individual users are responsible for determining the validity of any CBTI for individual test-takers, availability of such system information is critical. Bersoff and Hofer (1991) noted that in spite of the apparent conflict between the developer's proprietary interest in the product and the clinician's need to responsibly evaluate the service, open and critical review of tests and CBTIs is critical for ensuring the quality of such materials and upholding the profession's ethical code.

4.17.5.2 Basis for Scientific and Professional Judgments

Psychologists rely on scientifically and professionally derived knowledge when making both scientific and professional judgments. The Ethics Code (APA, 1992) also states explicitly that "Psychologists select scoring and interpretation services (including automated services) on the basis of evidence of the validity of the program and procedures as well as on other appropriate considerations" (p. 1604). While psychologists are clearly compelled to justify their professional statements and behavior with empirically derived evidence, the current state of CBTI development makes this a difficult task indeed. The overwhelming majority of automated interpretive programs lack even preliminary forms of established validity (Lanyon, 1984). With this concern in mind, Matarazzo (1986) insisted that until research establishes (even the most primitive) validity for CBTIs, "It is essential that they be used only as tools by the clinician trained in their use and not as equivalents of, and thus substitutes for, professional education and training" (p.14).

Empirical validation of CBTI systems is exceptionally difficult given the exhaustive range of potential test scores and profiles. As a result, there are no purely actuarial interpretive programs in existence (Butcher et al, 1985; Fowler, 1985). Instead, most CBTIs offer a form of automated clinical prediction (Graham, 1993) in which published research, clinical hypotheses, and clinical experience on the part of an "expert" clinician are integrated into interpretive narrative statements. Nonetheless, the validity of such statements cannot be assumed by users of such reports and must be demonstrated every bit as much as the validity of the test on which it is based. Psychologists who employ CBTI reports must clearly understand the basis for the statements offered by such services, their validity or lack thereof, and take reasonable steps to ensure that those with whom they work are not harmed by the irresponsible or uncritical use of such reports.

4.17.5.3 Describing the Nature of Psychological Services

In his review of the state of personality assessment for the *Annual Review of Psychology*, Lanyon (1984) offered a stern indictment of the CBTI industry. He noted that available literature regarding these programs appeared to come in three essential varieties. These included:

> (a) glossy promotional literature sometimes masquerading as scientific data and usually accompanied by sample records, (b) studies of customer and user satisfaction, which has never been much of a problem, and (c) an occasional paper giving actual information about the development or validation of an automated system. (p. 690)

Lanyon was particularly distressed by the fact that gross deficits in program validity appeared to have become the norm for CBTI systems. The primary ethical issue of concern here has to do with the manner in which psychologists describe and/or promote computerized assessment services. Two sections of the Ethics Code (APA, 1992) have particular relevance here. First, when describing the nature and results of psychological services, "Psychologists provide, using language that is reasonably understandable to the recipient of those services, appropriate information later about results and conclusions" (p. 1600). Second, the section on avoidance of false or deceptive statements emphasizes that psychologists refrain from making false, deceptive, or misleading statements either by virtue of what they convey or omit concerning their services and work activities. This emphasis on avoiding deception also extends to descriptions of the scientific or clinical basis for, or results or degree of success of psychologists services. The implication of these standards would suggest a rather clear mandate for psychologists to explicitly describe those CBTI services they participate in developing, promoting, or utilizing in their clinical work. This would include descriptions of the process by which the program was constructed, the manner in which it generates interpretive material and any existing evidence of validity. By the same token, psychologists must be proactive in highlighting deficits in system validity or performance such that consumers and users might avoid harmful outcomes. Finally, psychologists should avoid misuse of their influence in the promotion of CBTIs and other computerized assessment products. "They [Psychologists] are alert to and guard against personal, financial, social, organizational, or political factors that might lead to misuse of their influence" (APA, 1992, p. 1601). Endorsements by respected psychologists in the field of assessment are often coveted and highly promoted by product marketers. The Ethics Code clearly warns against irresponsible promotion of CBTI products in a manner which might compromise the profession or increase misuse of such materials by other professionals and consumers.

4.17.5.4 Competence

Establishing and maintaining an appropriate level of competence in the area of computerized psychological assessment may be one of the most significant areas of ethical risk for psychologists at this time. The Ethics Code (APA, 1992) makes numerous references to the importance of competence for psychologists. The first ethical principle in the Ethics Code relates to competence and stresses that psychologists maintain a high degree of competence in their work and clearly articulate the boundaries of their expertise. "Psychologists function only within boundaries of competence based on education, training and supervised experience or appropriate professional experience" (p. 1599). Further, they provide services in new areas of practice "only after first undertaking appropriate study, training, supervision and/or consultation from persons competent in those areas" (p. 1600). Initially establishing and demonstrating competence in the area of CAPA would not appear to be adequate, however, as psychologists are additionally enjoined by the Ethics Code to maintain their expertise as long as they practice as psychologists. "Psychologists maintain a reasonable level of awareness of current scientific and professional information in their fields of activity and undertake ongoing efforts to maintain competence in the skills they use" (p. 1600).

Development of clear standards and guidelines for use of CBTIs in particular will serve to protect consumers and the profession. They might also serve as critical guides to psychologists, judges, and the courts in determining the standard of practice in this area (Hofer & Green, 1985). Bersoff and Hofer (1991) noted that establishing a prevailing "standard of care" in the area of CBTIs is critical to determining whether a test program's user, developer, or publisher violated a prevailing standard and is therefore ethically out of compliance or legally culpable. Examples of such noncompliance might include negligent entry of data, selection of a scoring system the psychologist should know is inappropriate for a client or unreasonable reliance on interpretive material from a CBTI narrative report. Problematically, the wide availability of CBTI and other computerized assessment services to persons of varied professional and educational backgrounds (Fowler, 1985), has rendered development of guidelines for competence in this area quite difficult.

The current Ethics Code more explicitly addresses the practice of psychological assessment and offers a clearer picture of how "competence" in this area might be defined:

> Those who develop, administer, score, interpret or use psychological assessment instruments do so in a manner and for purposes that are appropriate in light of research or on evidence of the usefulness and proper application of the techniques ... Psychologists who perform interventions or administer, score, interpret, or use assessment techniques are familiar with the reliability, validation, and related standardization or outcome studies of and proper applications and uses of the techniques they use. (APA, 1992, p. 1603)

Although broad, the Ethics Code does suggest several primary areas in which psychologists should have reasonable expertise if they are to competently utilize computer generated assessment material in their work with clients.

As a result of the ethical requirement for practitioners to evaluate the soundness of CBTI reports, they must obviously be qualified to interpret the test themselves. This requires not only basic familiarity with psychometric principles but also a rather detailed understanding of the manner in which the particular system in question was developed and generates interpretive material. On the basis of this understanding, the psychologist might then be able to reject, modify, or expand reports for particular clients (Hofer & Green, 1985). Psychologists will need to be familiar with three components of the CBTI services they utilize in order to do this effectively. These include (i) the examinees score on the relevant test or scale, (ii) the test scale or combination of scales on which interpretations are based, and (iii) research or clinical evidence supporting the interpretation.

In addition to basic competence in psychometrics and interpretation of CBTI assessment findings for individual clients, psychologists must also demonstrate competence in the appropriate monitoring of CBTI data. The Ethics Code requires psychologists to make reasonable efforts to maintain the security of tests and other assessment techniques (APA, 1992). To do this effectively in the area of CAPA, psychologists must establish formal procedures for retaining, reviewing, and releasing computerized assessment data. Tranel (1994) noted that psychologists bear responsibility for determining whether those requesting test data are qualified to interpret it appropriately. The concern here relates to nonexperts drawing erroneous conclusions based on naive use of CBTI reports. It appears that psychologists must not only avoid irresponsible use of computerized test data themselves, but must also prevent the same on the part of others, "Psychologists do not misuse assessment techniques, interventions, results and interpretations and take reasonable steps to prevent others from misusing the information these techniques provide" (APA, 1992, p. 1603). Related to the release of test data is concern that test questions or CBTI system information may become part of the public domain, resulting in risk of invalidation of tests as well as potential violation of copyright laws and contractual obligations (APA, 1996; Tranel, 1994). Because many CBTI reports include printouts of the client's raw scores as well as those critical items endorsed, users must exercise the same approach to maintaining test security they might employ with any other form of test data.

4.17.5.5 Professional Context

Perhaps the most alluring and potentially dangerous property of CBTI narrative reports is their polished, professional, and thorough appearance. Psychologists, like other users of these services, may be tempted to rely excessively on information from such computerized narratives without adequate interaction with the individual client or reasonable consideration of the unique circumstances in which the client presents for evaluation. The Ethics Code (APA, 1992) rather clearly addresses this concern,

> Psychologists perform evaluations, diagnostic services or interventions only within the context of a defined professional relationship ... Psychologists' assessments, recommendations, reports and psychological diagnostic or evaluative statements are based on information and techniques (including personal interviews of the individual when appropriate) sufficient to provide appropriate substantiation for their findings. (p. 1603)

Most concur that computerized assessment narratives must be carefully reviewed for appropriateness and "fit" with the examinee in light of research, complete information about the examinee, and solid professional judgment (Carson, 1990; Fowler, 1985; Graham, 1993; Hofer & Green, 1985).

Matarazzo (1990) made the case that one of the primary sources of ethical and professional danger in this regard has been a rather subtle but progressive loss of distinction between psychological assessment as a professional activity and mere testing.

> Objective psychological testing and clinically sanctioned and licensed psychological assessment are vastly different, even though assessment usually includes testing ... Psychological assessment is engaged in by a clinician and a patient in a one-to-one relationship and has statutorily defined or implied professional responsibilities ... Specifically, it [assessment] is the activity of a licensed professional, an artisan familiar with the accumulated findings of his or her young science. (p. 1000)

Similarly, Carson (1990) called for defense of "clinicianship" (p. 437) within psychological assessment and highlighted many of the dangers inherent in considering CBTI data apart from other primary client information and without the benefit of a clear client–professional relationship. Those portions of the Ethics Code addressing utilization of assessment results and computerized scoring and interpretive services are clear that psychologists retain full responsibility for conducting competent and context appropriate assessment, versus context blind and potentially harmful psychological testing, "Psychologists retain appropriate responsibility for the appropriate application, interpretation and use of assessment instruments, whether they score and interpret such tests themselves or use automated or other services" (APA, 1992, p. 1604). A related but unresolved concern, however, is how psychologists are to retain such responsibility when most CBTI reports are not signed by a responsible psychologist. Matarazzo (1986) highlighted this problem:

> Although it is not yet part of psychology's code of ethics, my experience leaves no question that computerized clinical interpretations offered in a professional setting about a person's intellectual, personality, brain-behavior and other highly personal characteristics constitutes a legally and professionally significant invasion of privacy and requires at the least, that the individuals offering these clinical interpretations sign their names to such consultations just as is done in every other profession. (p. 21)

4.17.5.6 CAPA with Special Populations

Related to the foregoing concern regarding the professional context of assessment and the psychologist's responsibility for ensuring the accuracy and appropriateness of computer generated assessment material, is concern regarding the implications of CBTIs for special client populations. The APA Ethics Code requires sensitivity to and respect for human differences among examinees and clients. This includes sensitivity to differences across such domains as age, gender, race, ethnicity, national origin, religion, sexual orientation, disability, language, and socioeconomic status. The Ethics Code specifically states that psychologists "remain vigilant for situations in which adjustments must be made in administration or interpretation secondary to individual or contextual factors" (APA, 1992, p. 1603). The rather clear implication here is that computer-assisted interpretive system results must be passed through the clinician's own interpretive grid with an eye toward identification of demographic or contextual factors on the part of the client which might raise concern about the validity of the findings (Bersoff & Hofer, 1991). This of course demands that the psychologist understands, and has access to, differences in base rates for specific demographic groups with respect to both the test and the interpretive program in question.

As a result of the burgeoning of CBTI systems, the proliferation of unsatisfactory and typically invalidated systems and the widespread marketing of such systems to unqualified users, there have been frequent calls in the scholarly and professional literature for development of standards and regulations relative to computerized approaches to assessment (Burke & Normand, 1987). In 1986 the APA published a set of guidelines for practice by psychologists in this arena. *Guidelines for computer-based test interpretations* (APA, 1986) offered a set of brief and general aspirational guidelines for developers and users of computerized assessment techniques and products. Conscious of the foregoing summary of salient ethical concerns in the field of CAPA, we will now offer a synopsis of those guidelines with a focus on why such guidelines are significant and how they might be applied by psychologists.

4.17.6 GUIDELINES FOR USERS OF COMPUTER-BASED TESTS AND INTERPRETATIONS

The following guidelines are intended for those professionals who use computer-based testing and interpretive services with those to whom they provide services. Table 2 contains the APA Guidelines for users of computer-based tests and interpretations (APA, 1986) and will serve as an outline for the current discussion.

Table 2 Guidelines for users and developers of computer-based tests and interpretations.

Guidelines for users

Administration

1. Influences on test scores due to computer administration that are irrelevant to the purposes of assessment should be eliminated or taken into account in the interpretation of scores.
2. Any departure from the standard equipment, conditions, or procedures, as described in the test manual or administrative instructions, should be demonstrated not to affect test scores appreciably. Otherwise, appropriate calibration should be undertaken and documented (see Guideline 16).
3. The environment in which the testing terminal is located should be quiet, comfortable, and free from distractions.
4. Test items presented on the display screen should be legible and free from noticeable glare.
5. Equipment should be checked routinely and should be maintained in proper working condition. No test should be administered on faulty equipment. All or part of the test may have to be readministered if the equipment fails while the test is being administered.
6. Test performance should be monitored, and assistance to the test-taker should be provided, as is needed and appropriate. If technically feasible, the proctor should be signaled automatically when irregularities occur.
7. Test-takers should be trained on proper use of the computer equipment, and procedures should be established to eliminate any possible effect on test scores due to the test-taker's lack of familiarity with the equipment.
8. Reasonable accommodations must be made for individuals who may be at an unfair disadvantage in a computer testing situation. In cases where a disadvantage cannot be fully accommodated, scores obtained must be interpreted with appropriate caution.

Interpretation

9. Computer-generated interpretive reports should be used only in conjunction with professional judgment. The user should judge for each test-taker the validity of the computerized test report based on the user's professional knowledge of the total context of testing and the test-taker's performance and characteristics.

Guidelines for developers

Human factors

10. Computerized administration normally should provide test-takers with at least the same degree of feedback and editorial control regarding their responses that they would experience in traditional testing formats.
11. Test-takers should be clearly informed of all performance factors that are relevant to the test result.
12. The computer testing system should present the test and record responses without causing unnecessary frustration or handicapping the performance of test-takers.
13. The computer testing system should be designed for easy maintenance and system verification.
14. The equipment, procedures, and conditions under which the normative, reliability, and validity data were obtained for the computer test should be described clearly enough to permit replication of these conditions.
15. Appropriate procedures must be established by computerized testing services to ensure the confidentiality of the information and the privacy of the test-taker.

Psychometric properties

16. When interpreting scores from the computerized versions of conventional tests, the equivalence of scores from computerized versions should be established and documented before using norms or cutting scores obtained from conventional tests. Scores from conventional and computer administrations may be considered equivalent when the rank orders of scores of individuals tested in alternative modes closely approximate each other, and the means, dispersions, and shapes of the score distributions are approximately the same, or have been made approximately the same by rescaling the scores from the computer mode.
17. The validity of the computer version of a test should be established by those developing the test.
18. Test services should alert test users to the potential problems of nonequivalence when scores on one version of a test are not equivalent to the scores on the version for which norms are provided.
19. The test developer should report comparison studies of computerized and conventional testing to establish the relative reliability of computerized administration.
20. The accuracy of computerized scoring and interpretation cannot be assumed. Providers of computerized test services should actively check and control the quality of the hardware and software, including the scoring, algorithms, and other procedures described in the manual.
21. Computer testing services should provide a manual reporting the rationale and evidence in support of computer-based interpretation of test scores.

Table 2 (continued)

Classification

22. The classification system used to develop interpretive reports should be sufficiently consistent for its intended purpose (see Chapter 2 of the 1985 *Testing Standards*). For example, in some cases it is important that most test-takers would be placed in the same groups if retested (assuming the behavior in question did not change).
23. Information should be provided to the users of computerized interpretation services concerning the consistency of classifications, including, for example, the number of classifications and the interpretive significance of changes from one classification to adjacent ones.

Validity of computer interpretations

24. The original scores used in developing interpretive statements should be given to test users. The matrix of original responses should be provided or should be available to test users on request, with appropriate considerations for test security and the privacy of test-takers.
25. The manual or, in some cases, interpretive report, should describe how the interpretive statements are derived from the original scores.
26. Interpretive reports should include information about the consistency of interpretations and warnings related to common errors of interpretation.
27. The extent to which statements in an interpretive report are based on quantitative research vs. expert clinical opinion should be delineated.
28. When statements in an interpretive report are based on expert clinical opinion, users should be provided with information that will allow them to weigh the credibility of such opinion.
29. When predictions of particular outcomes or specific recommendations are based on quantitative research, information should be provided showing the empirical relationship between the classification and the probability of criterion behavior in the validation group.
30. Computer testing services should ensure that reports for either users or test-takers are comprehensible and properly delimit the bounds within which accurate conclusions can be drawn by considering variables such as age or sex that moderate interpretations.

Review

31. Adequate information about the system and reasonable access to the system for evaluating responses should be provided to qualified professionals engaged in a scholarly review of the interpretive service. When it is deemed necessary to provide trade secrets, a written agreement of nondisclosure should be made.

4.17.6.1 Administration

Guidelines 1–8 clearly address the responsibility of the computerized system's user in ensuring that examinees are not adversely affected by the computerized administration itself. The environment must be conducive to comfort and maximal performance on the part of the examinee and extraneous influences on his or her performance should be minimized. While computerized administration generally appears to enhance the ease of test taking while decreasing overall time required (Green, 1991b), such programs should routinely assess for evidence that the examinee understands tests and procedures. If an examinee demonstrates any reservation or apprehension regarding interacting with a computer, a conventional format version of the test should be substituted when possible. In the future, a good deal more research is needed to better understand the impact of computers on examinee experience of the assessment process, satisfaction with the experience, and response to the results generated (Finn & Butcher, 1991).

4.17.6.2 Evaluation and Selection of CBTIs

The potential for profound misuse of testing material exists when individuals without adequate training are granted access to automated interpretive systems (Butcher, 1987). When the CBTI user is not a psychologist or lacks the background to effectively and reliably interpret tests, danger exists that CBTIs will not be appropriately scrutinized and carefully selected for the client in question. Moreland, Eyde, Robertson, Primoff, and Most (1995) reported on an attempt to establish basic test user qualifications. The authors found that the 86 identified testing competencies could be distilled to 12 "minimum competencies" and that these could be further reduced to two major categories of competence. Test-users must (i) possess adequate knowledge of the test (or test scoring and interpretation program) and its limitations, and (ii) accept responsibility for the competent use of the test (or computerized test program). Competent use of CBTIs requires that the psychologist carefully evaluate and select appropriate and reasonably validated interpretive programs.

Although well-designed interpretive programs which utilize a careful compilation of empirical data and expert opinion often yield more valid interpretive reports than those generated by clinicians (Green, 1991b), users must become familiar with and conversant regarding the program's established validity. Nonetheless, determining acceptable levels of validity for automated reports poses two problems. First, many tests themselves lack adequate development research and second, most interpretive programs have no established validity themselves or very little (Butcher, 1987). Therefore, it is critical for the prospective user to review the test manual, related documentation, and examples of the computerized reports prior to utilizing them with clients. It is particularly important to evaluate the system rationale for interpreting scores and profiles. How well are the classification and decisional criteria operationalized? Potential users are also encouraged to evaluate the credentials of the system's authors (Lanyon, 1987) and consider the authors' standing as both an expert clinician and a scholar in the field of CBTI.

Another basis on which to evaluate the potential value of a CBTI is that of general utility. As a rule, the rationale or justification for conducting an assessment hinges on provision of information of value with respect to planning and executing treatment (Hayes, Nelson, & Jarrett, 1987). A CBTI will have utility to the extent there is evidence that it contributes to positive treatment outcome, or in some way enhances the status of individuals for whom it is employed. Those systems high in utility will generally be highly efficient and usable, time and cost-effective, and able to discriminate effectively such that real between-examinee differences are detected (Krug, 1987).

Finally, Ben-Porath and Butcher (1986) offered several questions which might be utilized by prospective users of CBTI systems determining which system to employ. We believe these questions offer a good summary of the major concerns expressed in these guidelines. They include (i) to what extent has the validity of the reports been established? (ii) to what extent do the reports rely on empirical findings in generating interpretations? (iii) to what extent do the reports incorporate all of the currently available validated descriptive information? (iv) do the reports take demographic variables into account? (v) are different versions of the report available for different referral questions? (vi) do the reports include practical suggestions? and (vii) are the reports periodically revised to reflect newly acquired information?

4.17.6.3 Interpretation

The APA guidelines (APA, 1986) are clear in warning that CBTIs should never be used as a singular indicator of a person's characteristics, psychological functioning, or diagnosis. Rather, professional judgment is required to determine the extent to which the computerized report is valid and appropriate in light of the total context of testing and test-taker's specific performance and characteristics. Many CBTI program developers and users express similar concern about the danger inherent in divorcing the skilled psychologist from the interpretation and use of computerized reports (Bersoff & Hofer, 1991; Butcher, 1987; Finn & Butcher, 1991; Groth-Marnat & Schumaker, 1989). The polished and objective appearance of narrative reports may lend to the temptation to accept them as valid without adequate scrutiny of their match with the examinee. Bersoff and Hofer (1991) noted

> There must be an interposition of human judgment between the CPTI report and decision making to ensure that decisions are made with full sensitivity to the nuances of test administration and interpretation, and that the unique constellation of attributes in each person is evaluated. (p. 241)

Responsible assessment will necessarily involve a multistep process (Finn & Butcher, 1991) in which computerized assessment results are skillfully integrated with other sources of information about the examinee. Currently, computers are not capable of offering a sophisticated synthesis of psychological test results. This integrative function appears to be squarely within the purview and professional responsibility of the psychological diagnostician. Without such integration, psychological reports are necessarily overly general, nonspecific, and questionably accurate. They would certainly fail to capture the test-taker's cognitive, affective, and behavioral functioning across a variety of situations (Bersoff & Hofer, 1991).

The prevailing standard ethically and legally appears to be that the computer-based report is a professional-to-professional consultation (Butcher, 1987). In this way, the computer is merely the equivalent of a library or consultant which might offer the most frequently indicated inferences or correlates for specific test scores or profiles. With the computer as librarian or "look up table" (Butcher, 1987, p. 9), the final determiner of the accuracy and adequacy of the computer-based report is the psychologist who receives the report.

An excellent example of adherence to this guideline is offered by Finn & Butcher (1991) who quote the disclaimer from the Clinical Interpretive Report for the MMPI. This disclaimer is printed on each interpretive report and highlights for users how the report should be utilized, "This MMPI interpretation can serve as a useful source of hypotheses about clients ... the personality descriptions, inferences, and recommendations contained herein need to be verified by other sources of clinical information since individual clients may not fully match the prototype" (p. 367).

4.17.7 GUIDELINES FOR DEVELOPERS OF COMPUTER-BASED TEST SERVICES

The following guidelines apply most directly to those involved in the construction, validation, and marketing of computerized assessment systems for use by others. Table 2 contains the guidelines for developers of computer-based test services (APA, 1986).

4.17.7.1 Human Factors

Guidelines 10–15 suggest developers of CAPA systems are broadly responsible to ensure that computerized administration of tests does not hamper the examinees' performance in any way. Examinees must also maintain reasonable control of the testing process and the testing service must assume full responsibility for establishing appropriate procedures for ensuring the confidentiality of data collected and the privacy of the examinee. This may be particularly challenging in light of the development of on-line test scoring and interpretation services. On-line access to client information must be carefully controlled by the testing service.

4.17.7.2 Psychometric Properties

Guidelines 16–21 in Table 2 require test or CBTI program developers to carefully evaluate and communicate the psychometric quality of the test or computerized interpretive system. When developing computerized versions of conventional tests, norms and cutting scores for the conventional test can only be used if the computer and conventional form are found to be equivalent (Green, 1991b). Not only should correlations between the two versions be high, but score distributions must be generally equivalent as well. Developers are expected to communicate results of equivalency studies to prospective users and to take initiative in "alerting" users to potential problems resulting from nonequivalence between forms.

4.17.7.3 Classification Strategy

When a computerized assessment system utilizes a classification system based on cutting scores, system developers must offer a convincing rationale for the particular system adopted and the cutting scores selected. In order for a CBTI system to be fully actuarial, system output is determined solely by statistical regularities that have been empirically demonstrated to exist between input and output data (Moreland, 1985). Instead, most systems combine actuarial and clinical expertise approaches. Users must be aware of the system strategy for integrating statistical and clinical prediction in the service of classifying examinees. Additionally, developers bear responsibility for communicating to users the consistency of the classification system and the meaning associated with changes between categories.

4.17.7.4 Validity of Computer Interpretations

As indicated by Guidelines 24–30, developers of computer-based test services are responsible for communicating information to users concerning the system's validity. Not only should validity data be made available to users, but developers must also clarify the extent to which interpretive statements are based on expert clinical opinion or quantitative research. Users must be shown the connection between such research or clinical opinion and specific interpretive statements and classification decisions. Further, developers are to warn users of common errors and potential pitfalls associated with the interpretive system. One of the reasons for the pervasive problem with establishing the validity of CBTI systems has to do with the practice of utilizing clinician generated reports as the criterion in validity research (Moreland, 1985). At times, computer reports may be more accurate than their clinician generated counterparts, thus falsely lowering validity coefficients. Developers should consider alternative criterion variables when possible.

Lanyon (1987) described six factors which should be considered by CBTI system developers in the service of increasing the validity of CBTI programs. First, reliability coefficients for both predictor and criterion variables have been unacceptably low for most CBTIs and should be increased. Second, in balancing the "bandwidth-fidelity" tension, CBTI developers should develop test indices that lead to single, focused predictions (narrow bandwidth/high-fidelity) versus trying to say too much from too little data. Third, departures from empirical data should be minimized. When test interpretations are based on data without attempts to polish, cluster, or otherwise alter them for the sake of appearance, errors in interpretation are minimized. Fourth, unwarranted generalizations from the standardization sample of CBTIs is a major source of invalidity. When the gap between the population from which an interpretive system was derived and the population on which it is used is substantial, validity declines and erroneous interpretations abound. Fifth, Lanyon recommends that an "unclassifiable" option be vigorously employed. Adding such a category (versus forcing predictive or interpretive statements for every profile) substantially enhances system validity. Finally, whenever possible, different base rates for characteristics being predicted or described should be employed in the interpretive system.

4.17.7.5 Facilitation of Review

The APA guidelines (APA, 1986) highlight the requirement for CBTI system developers to provide adequate information about the system as well as reasonable access to this information on the part of qualified professionals engaged in reviewing the interpretive system. Previous reviewers of this topic appear to concur that availability of detailed development information and data is critical to responsible evaluation of CBTI systems and their usefulness to clinicians (Green, 1991b; Lanyon, 1987; Roid & Gorsuch, 1984; Snyder et al., 1990). High quality interpretive programs clearly label the program using standardized descriptions which clarify the function of the system and the specific manner in which it generates interpretive statements. Such programs provide detailed data relative to development of the system and extensive references to the empirical basis for the decision rules used.

4.17.8 DIRECTIONS FOR THE FUTURE

Various authors have speculated about the future role and developmental course of CAPA. These have included highly optimistic outlooks such as that of Moreland (1985), "I am confident that the computer will eventually replace the professional for most, but not all, assessment functions ... and this may happen sooner rather than later" (p. 229), as well as more pessimistic perspectives based on fears about the dehumanization of the assessment process (Matarazzo, 1986).

A primary problem in the development in CAPA is the substantial lag in "psychotechnology" currently evident in the assessment field. Specifically, our understanding of assessment appears to lag behind available computer technology. Along these lines, there is a rather profound need for better research designs and demonstrations of program validity (Lanyon, 1984) among CBTI systems. Currently, a number of such programs offer little in the way of adherence to APA (1986) guidelines for development of CBTI software.

Hopefully, the future holds more promise for empirical research on the reliability and validity of CBTI systems. As more powerful desk-top (and lap-top) computers expand, increasingly complex statistical analyses are possible for test developers who have the expertise to use them. No longer is computer power located in a small number of central or "mainframe" facilities. Greater resources and more creativity in research designs for the study of CBTI are certainly needed. Creative methods of linking test and nontest data, in cost-effective formats, will also be crucial to the development and long-term refinement of CBTI. Test developers should study the classic examples given by Lachar (1984) and the methods reviewed by Snyder et al. (1990) and find ways to connect clinician's ratings, medical and treatment histories, and demographic data to the test-score data file. An important area of expansion in neuropsychological assessment will be the connection of imaging technology (e.g., magnetic resonance imaging [MRI] results) to psychological and cognitive test scores.

Alternatively, the field of CBTI should shift more toward a model of computer as "research assistant" (Roid, 1985), and provide methods for the clinician to access research findings, empirical correlates, and, perhaps, brief and verifiable narrative descriptions such as symptom lists from clinician checklists. However, in the "assistant" model, the final selection and control of narrative statements would be retained as a function of the clinician, not the computer program. As mentioned previously, the word-processing capabilities of systems such as WISC-III Writer (Psychological Corporation, 1994) should make correlated empirical findings available in a "scrapbook" but not be automatically printed in a report. Such systems could become even more elaborate in the future, employing extensive database functions and multimedia graphics, to supplement the conventional test-score results. Much could be done in the future to have even more demographic and historical data available for each client, as long as privacy is protected. The control of the assembly, selection, and composition of the final collection of, for example, data, statements, and graphs, should remain in the hands of the experienced clinician.

Another area of future development will surely be in the expansion of the multimedia capability of CAPA programs. All types of CAPA, from administration to scoring to interpretation could employ more sophisticated graphic and, perhaps, video capability. Gregory (1996) reports on the development of multimedia "situational" tests being developed at IBM that depict actual on-the-job scenes. The computer may briefly "pause" a video display and ask the examinee to answer questions, or predict the "next step" in the scenario, for purposes of assessing the examinee's sensitivity to interpersonal or technical concerns on the job. For example, the senior author of this chapter assisted in a research project to develop qualification tests for parole officers who were being screened for ability to perform "combative arrests." Film and audio depictions of scenarios with real parole officers were studied to identify critical behaviors such as advanced planning of back-up assistance, prediction of the parolee's potential route in the event of an escape attempt, and physical strategy for placing handcuffs on the subject. Extensive studies of physical movements involved in arrest scenarios were conducted to determine hand and arm strengths required. However, it became clear that many skills were "cognitive" rather than physical and included skills such as planning, prediction, and knowledge of typical parolee strategies of escaping arrest. Such an evaluation might be depicted on computerized video collections, shown to potential applicants, and present questions of strategy and planning. Clearly, extensive empirical validation with actual parole officers, including those who were previously judged to be "expert" in combative arrest, would be essential to the development of such a system. The key element of this "futuristic" system would be the video reenactments, presented on multimedia computer equipment—a method of simulation that has been available on motion-picture film for decades. In the future, more precise computer-adaptive testing may be possible for this medium.

One of the more promising areas for future development is that of adaptive testing. By administering only those test items necessary to draw supportable clinical conclusions, psychologists should be able to substantially reduce testing time while enhancing both the reliability and validity of findings (Krug, 1987). Computer-generated and tailor-made personality tests are a particularly interesting possibility.

Finally, the debate regarding the role of computers in the assessment process will certainly continue in the future around the issue of the role of the clinical psychologist. Butcher (1987) noted

> As interest in developing integrated clinical diagnostic reports broadens, more research or system adequacy will be stimulated, and, no doubt, more intense dialogue will be generated on the appropriateness of machines to perform what is believed by some to be an essentially human activity. (p. 11)

4.17.9 CONCLUSIONS AND RECOMMENDATIONS

In summary, the best recommendation for clinical practice, given the current state of validation of narrative computer-interpretive programs is for clinicians to "draw a line" between scoring programs and narrative-interpretive programs. Computer administration of tests and scoring (including elaborate statistical scoring and graphical display) can clearly assist the clinician in terms of efficient use of time and accuracy of calculation. Unless the following conditions are satisfied, it is recommended that CBTI programs with extensive narrative reports be used only for hypothesis generation and never as an unedited section of a psychological report:

(i) *Clinician retains control of word/sentence selection.* If the narrative program gives control to the clinician for assembly of narrative descriptions, then the unique situation of the client can be used to temper the assessment narrative. Automatically printed statements should never be used unedited. Thus, CBTI programs should be "research assistants," not "automated interpreters."

(ii) *Test developers apply actuarial research and document it.* The technical manual accompanying CBTI programs should clearly describe the details of the empirical validation of all descriptive statements, list all cutting scores and their validation studies, present classification accuracy statistics for all profile rules employed, and provide cautionary statements of study limitations.

(iii) *Researchers of CBTI should develop more cost-effective research designs.* Given that the cost of validation is a frequent excuse given for lack of empirical study, statisticians and research experts are encouraged to creatively design new types of studies in cooperation with CBTI developers so the field of CAPA can advance on a more scientific basis where possible.

(iv) *Psychologists should be vigilant in distinguishing assessment from testing.* In the interests of preventing the erosion of the meaning of clinical assessment, as emphasized by Matarazzo (1986, 1990), all psychologists should be alerted to the concern that the final evaluation of all relevant client information, including the context, history, and uniqueness of the client, be reserved for the experienced, trained clinician, not the computer.

4.18.1 INTRODUCTION

The cost of health care in the USA has reached astronomical heights. In 1995, approximately $1 trillion, or 14.9% of the gross domestic product, was spent on health care, and a 20% increase is expected by the year 2000 (*Mental Health Weekly*, 1996a). The cost and prevalence of mental health problems and the accompanying need for behavioral health care services in the USA continue to rise at rates which give cause for concern. America's mental health bill in 1990 was $147 billion (*Mental Health Weekly*, 1996c). The Center for Disease Control and Prevention (1994) recently reported on the results of a survey of 45 000 randomly interviewed Americans regarding their quality of life. The survey found that one-third of the respondents reported they suffered from depression, stress, or emotional problems at least one day a month, and 11% percent of the sample reported having these problems more than eight days a month.

The American Psychological Association (APA; 1996) also reports statistics, summarized below, that bear attention.

(i) It is estimated that 15–18% of Americans suffer from a mental disorder; 14 million of these individuals are children.

(ii) Approximately eight million Americans suffer from depression in any given one-month period.

(iii) As many as 20% of Americans will suffer one or more major episodes of depression during their lifetime.

(iv) An estimated 80% of elderly residents in Medicaid facilities were found to have moderate to intensive needs for mental health services.

Moreover, information from various studies indicates that at least 25% of primary health care patients have a diagnosable behavioral disorder (*Mental Health Weekly*, 1996b).

The need for behavioral health care services is significant. In analyzing data from a 1987 national survey of 40 000 people in 16 000 households, Olfson and Pincus (1994a, 1994b) found that 3% of the population was seen for at least one psychotherapeutic session that year. Of these visits, 81% were to mental health professionals. Estimates provided by VandenBos, DeLeon, and Belar (1993) in the early 1990s indicated that in any year, 37.5 million Americans (or 15% of the population at that time) could benefit from mental health services.

What is the value of the services provided to those suffering from mental illness or substance abuse/addiction/dependency? Some might argue that the benefit is either minimal, or too costly to achieve if significant effects are to be gained. This is in the face of data which suggest otherwise. Numerous studies have demonstrated that treatment of mental health and substance abuse/dependency problems can result in substantial savings when viewed from a number of perspectives. This "cost offset" effect probably has been demonstrated most clearly in savings in medical care dollars over given periods of time.

Medical cost offset considerations are significant, given reports that 50–70% of usual primary care visits are for medical problems that involve psychological factors (APA, 1996). APA also reports that 25% of patients seen by primary care physicians have a disabling psychological disorder, and that depression and anxiety rank among the top six conditions seen by family physicians. Following are just a few of the findings supporting the medical cost benefits that can accrue from providing behavioral health care treatment.

(i) At least 25% or more of patients seen in a primary care setting have diagnosable behavioral disorders and use two to four times as many medical resources as those patients without these disorders (*Mental Health Weekly*, 1996b).

(ii) Sipkoff (1995) reported several conclusions, drawn from a review of numerous studies conducted between 1988 and 1994 and listed in the *Cost of addictive and mental disorders and effectiveness of treatment* report published by the Substance Abuse and Mental Health Services Administration (SAMHSA). One conclusion derived from a meta-analysis of offset effect was that treatment for mental health problems results in an approximately 20% reduction in the overall cost of health care. The report also concluded that while alcoholics were found to spend twice as much on health care as those without abuse problems, one-half of the cost of substance abuse treatment is offset within one year by subsequent reductions in the combined medical cost savings for the patient and his or her family.

(iii) Strain et al. (1991) found that screening a group of 452 elderly hip fracture patients for psychiatric disorders prior to surgery and providing mental health treatment to the 60% of the sample needing treatment reduced total medical expenses by $270 000. The cost of the psychological/psychiatric services provided to this group was only $40 000.

(iv) Simmons, Avant, Demski, and Parisher (1988) compared the average medical costs for chronic back pain patients at a multidimensional pain center (providing psychological and other types of intervention) during the year prior to treatment to those costs of the year following treatment. The pretreatment costs per patient were $13 284 while post-treatment costs were $5596.

The reader is referred to Friedman, Sobel, Myers, Caudill, and Benson (1995) for a detailed discussion of various ways in which behavioral interventions can both maximize care to medical patients and achieve significant economic gains.

APA (1996) has very succinctly summarized what appears to be the prevalent findings of the medical cost offset literature.

> (i) Patients with mental disorders are heavy users of medical services, averaging twice as many visits to their primary care physicians as patients without mental disorders.
>
> (ii) When appropriate mental health services are made available, this heavy use of the system often decreases, resulting in overall health savings.
>
> (iii) Cost offset studies show a decrease in total health care costs following mental health interventions even when the cost of the intervention is included.
>
> (iv) In addition, cost offset increases over time, largely because ... patients continue to decrease their overall use of the health care system, and don't require additional mental health services. (p. 2)

Medical cost offset effects are relatively obvious and easy to measure. Benefits, financial and otherwise, that accrue from the treatment of mental health and substance abuse/dependency problems also can come in forms that may not be so obvious. One area in which treatment can have a tremendous impact is that of the workplace. For example, note a few of the facts assembled by APA (1996).

(i) In 1985 behavioral health problems resulted in over $77 billion in lost income to Americans.

(ii) California's stress-related disability claims totaled $350 million in 1989.

(iii) In 1980, alcoholism resulted in over 500 million lost work days in this country.

(iv) Major depression cost an estimated $23 billion in lost work days in 1990. In addition, individuals with this disorder are three times more likely than nondepressed individuals to miss time from work and four times more likely to take disability days.

(v) Of all subjects from 58 psychotherapy effectiveness studies focusing on the treatment of depression, 77% received significantly better work evaluations than depressed subjects who did not receive treatment.

(vi) Treatment resulted in a 150% increase in earned income for alcoholics and a 390% increase in income for drug abusers in one study of 742 substance abusers.

In related findings, anxiety disorders accounted for one-third of America's $147 billion mental health bill in 1990 (*Mental Health Weekly,* 1996c). And on another front, the former director of the Office of the National Drug Control Policy reported that for every dollar spent on drug treatment, America saves seven dollars in health care and criminal justice costs (*Substance Abuse Funding News*, 1995).

Society's need for behavioral health care services provides an opportunity for trained providers of mental health services to become part of the solution to a major health care problem that shows no indication of decline. Each of the helping professions has the potential to make a particular contribution to this solution. Not the least of these contributions are those that can be made by clinical psychologists. As pointed out in an earlier volume (Maruish, 1994), the use of psychological tests in the assessment of the human condition is one of the hallmarks of clinical psychology. In fact, the training and acquired level of expertise in psychological testing distinguishes the clinical psychologist from other behavioral health care professionals probably more than anything else. Indeed, expertise in test-based psychological assessment can be said to be the particular and unique contribution that clinical psychologists make to the behavioral health care field.

For decades, clinical psychologists and other behavioral health care providers have come to rely on psychological assessment as a standard tool to be used with other sources of information for diagnostic and treatment planning purposes. However, changes that have taken place in the delivery of health care in general, and behavioral health care services in particular, during the past several years have led to changes in the way in which third-party payers and clinical psychologists themselves think about and/or use psychological assessment in day-to-day clinical practice. Some question the value of psychological assessment in the current time-limited, capitated service delivery arena where the focus has changed from clinical priorities to fiscal priorities (Sederer, Dickey, & Hermann, 1996). Others argue that it is in just such an arena that the benefits of psychological assessment can be most fully realized and contribute significantly to the delivery of cost-effective treatment for behavioral health disorders. Consequently, it could assist the health care industry in appropriately controlling or possibly reducing the utilization and cost of health care over the long term. It is this latter side of the argument that is supported by this author, and it provides the basis for this chapter.

In developing this chapter, the intent has been to provide students and practitioners of clinical psychology with an overview of how psychological assessment could and should be used in this era of managed behavioral health care. In doing so, this author discusses how psychological assessment is currently being used in the therapeutic environment and the many ways in which it might be used to the ultimate benefit of patients, providers, and payers.

As a final introductory note, it is important for the reader to understand that the term "psychological assessment," as it is used in this chapter, refers to the evaluation of a patient's mental health status using psychological tests or related instrumentation. This evaluation may be conducted with or without the benefit of patient or collateral interviews, review of medical or other records, and/or other sources of relevant information about the patient.

4.18.2 THE CURRENT PRACTICE OF PSYCHOLOGICAL ASSESSMENT IN THE THERAPEUTIC ENVIRONMENT

For a number of decades, psychological assessment has been viewed as a valued and integral part of the services offered by clinical psychologists. However, its popularity has not been without its ups and downs. Megargee and Spielberger (1992) have described a decrease in interest in assessment that began in the 1960s. This was due to a number of factors, including shifts in focus to those aspects of treatment for which assessment was thought to contribute little. Examples of these aspects included a growing emphasis on behavior modification techniques, the increasing use of psychotropic medications, and an emphasis in studying symptoms rather than personality syndromes and structures. Fortunately, Megargee and Spielberger also noted a number of factors that indicate a relatively recent resurgence in the interest in assessment, including a new realization of how psychological assessment can assist in interventions provided to mental health care patients.

But where does psychological assessment actually fit into the daily scope of activities for practicing psychologists? The results of two recent surveys provide inconsistent findings. The newsletter *Psychotherapy Finances* (1995) reported the results of a nationwide readership survey of 1700 mental health providers of various professions. In this survey, 67% of the participating psychologists reported that they provide psychological testing services. This represents about a 10% drop from a similar survey published in 1992 by the same publication. Also of interest in this survey is the percent of professional counselors (39%), marriage and family counselors (16%), psychiatrists (21%), and social workers (13%) offering these same services.

In a 1995 survey conducted by the APA's Committee for the Advancement of Professional Practice (Phelps, 1996), 14 000 practitioners responded to questions related to workplace settings, areas of practice concerns, and range of activities. Most of the respondents (40.7%) were practitioners whose primary work setting was an individual independent practice. Other general work settings, that is, government, medical, academic, group practice settings, were represented by fairly equal numbers of respondents from the remainder of the sample. The principal professional activity reported by the respondents was psychotherapy, with 43.9% of the sample acknowledging involvement in this service. Assessment was the second most prevalent activity, being reported by 14% of the sample.

Differences in the two samples utilized in the above surveys may account for the inconsistencies in their findings. Psychologists who are subscribers to *Psychotherapy Finances* may represent that subsample of the APA survey respondents who are more involved in the delivery of clinical services. Certainly the fact that only about 44% of the APA respondents offer psychotherapy services supports this hypothesis.

Regardless of the two sets of findings, psychological assessment does not appear to be utilized as much as in the past, and one does not have to look hard to determine at least one reason why. One of the major changes that has come about in the American health care system during the past several years has been the creation and proliferation of managed care organizations (MCOs). The most significant direct effects of managed care include reductions in the length and amount of service, reductions in accessibility to particular modalities (e.g., reduced number of outpatient visits per case), and profession-related changes in the types of services managed by behavioral health care providers (Oss, 1996). Overall, the impact of managed behavioral health care on the services offered by psychologists and other health care providers has been tremendous. In the APA survey reported above (Phelps, 1996), approximately 79% of the respondents reported that managed care had either a low, medium, or high negative impact on their work. How has managed care negatively impacted the use of psychological assessment? It is not clear from the results of this survey, but perhaps others can offer at least a partial explanation.

Ficken (1995) has provided some insight into how the advent of managed care has limited the reimbursement for (and therefore the use of) psychological assessment. In general, he sees the primary reason for this as being a financial one. In an era of capitated behavioral health care coverage, the amount of money available for behavioral health care treatment is limited. MCOs therefore require a demonstration that the amount of money spent for testing will result in a greater amount of treatment cost savings. In addition, Ficken notes that much of the information obtained from psychological assessment is not relevant to the treatment of patients within an MCO environment. Understandably, MCOs are reluctant to pay for the gathering of such information.

Werthman (1995) provides similar insights into this issue, noting that

> Managed care … has caused [psychologists] to revisit the medical necessity and efficacy of their testing practices. Currently, the emphasis is on the use of highly targeted and focused psychological and neuropsychological testing to sharply define the "problems" to be treated, the degree of impairment, the level of care to be provided and the treatment plan to be implemented.
>
> The high specificity and "problem-solving" approach of such testing reflects MCOs' commitment to effecting therapeutic change, as opposed to obtaining a descriptive narrative with scores. In this context, testing is perceived as a strong tool for assisting the primary provider in more accurately determining patient "impairments" and how to "repair" them. (p. 15)

In general, Werthman views psychological assessment as being no different from other forms of patient care, thus making it subject to the same scrutiny, demands for demonstrating medical necessity and/or utility, and consequent limitations imposed by MCOs on other covered services.

The foregoing representations of the current state of psychological assessment in behavioral health care delivery could be viewed as an omen of worse things to come. In this author's opinion, they are not. Rather, the limitations that are being imposed on psychological assessment and the demand for justification of its use in clinical practice represent part of the customers' dissatisfaction with the way things always have been done in the past. In general, this author views the tightening of the purse strings as a positive move for both behavioral health care and the profession of psychology. It is a wake-up call to those who have contributed to the health care crisis by either uncritically performing costly psychological assessments, being unaccountable to the payers and recipients of our services, and generally not performing our services in the most responsible, cost-effective and efficient way possible. It is telling us that we need to evaluate what we've done and the way we've done it, and to determine what is the best way to do it in the future. As such, it provides an opportunity for clinical psychologists to re-establish the valuable contributions they can make to improving the quality of behavioral health care delivery through their knowledge and skills in the area of psychological assessment.

In the sections that follow, this author will convey what he sees are the opportunities for psychological assessment in the behavioral health care arena, both in the present and the future, and the means of best achieving them. The views that are advanced are based on his knowledge of and experience in current psychological assessment practices as well as directions provided by the current literature. Some will probably disagree with the proposed approach, given their own experience and thinking on the matters discussed. However, it is hoped that even though in disagreement, the reader will be challenged to defend his or her position to themselves and as a result, feel more comfortable in their thinking about their approach to their psychological assessment practices.

4.18.3 PSYCHOLOGICAL ASSESSMENT AS A THERAPEUTIC ADJUNCT

The role of psychological assessment in the therapeutic environment traditionally has been quite limited. Those of us who did not receive our graduate clinical training within the past few years probably have been taught the value of psychological assessment only at the "front end" of treatment. We were instructed in the power and utility of psychological assessment as a means of assisting in the identification of symptoms and their severity, personality characteristics relevant to understanding the patient and his or her typical way of perceiving and interacting with the world, and other aspects of the individual (e.g., intelligence, vocational interests) that are important in arriving at a description of the patient at one particular point in time. Based on these data and information obtained from patient and collateral interviews, medical records and the individual's stated goals for treatment, a diagnostic impression was given and a treatment plan was probably formulated and placed in the patient's chart, hopefully to be reviewed at various points during the course of treatment. In some cases, the patient was assigned to another practitioner within the same organization or referred out, never to be contacted or seen again, much less be assessed again by the one who performed the original assessment.

Fortunately, during the past few years the usefulness of psychological assessment as more than just a tool to be used at the beginning of treatment has come to be recognized. Consequently, its utility has been extended beyond being a mere tool for describing an individual presenting themselves for treatment to being a means of facilitating the treatment and understanding of behavioral health care problems throughout the episode of care and beyond. Psychologists and others who employ it in their practices are now finding that psychological assessment can be used for a variety of purposes. Generally speaking, several psychological tests currently being marketed can be employed as tools for assisting in clinical decision-making, outcomes assessment and, more directly, as treatment techniques in and of themselves. Each of these uses can uniquely contribute incremental value to the therapeutic process.

4.18.3.1 Psychological Assessment for Clinical Decision-making

Traditionally, psychological assessment has been used to assist clinical psychologists and other behavioral health care clinicians in making important clinical decisions. The types of decision-making for which it has been used include those related to screening, treatment planning, and monitoring of treatment progress. Generally, screening may be undertaken to assist in either: (i) identifying the patient's need for a particular service, or (ii) determining the likelihood of the presence of a particular disorder or other behavioral/emotional/psychological problem. More often than not, a positive finding on screening leads to a more extensive evaluation of the patient in order to confirm with greater certainty the existence of the problem, or to further delineate the problem. The value of screening lies in the fact that it permits the clinicians to identify, quickly and economically, with a fairly high degree of confidence (depending on the particular instrumentation used), those who are and are not likely to need care or at least further evaluation.

In many instances, psychological assessment is performed in order to obtain information that is deemed useful in the development of a specific plan for treatment. Typically, it is the type of information that is not easily (if at all) accessible through other means or sources. It is information which, when combined with other information about the patient, aids in understanding the patient, identifying the most important problems and issues that need to be addressed, and formulating recommendations about the best means of addressing them.

Another way in which psychological assessment can play a role in clinical decision-making is in the area of treatment monitoring. Repeated assessment of the patient at regular intervals during the treatment process can provide the therapist with feedback regarding the progress which is being made in the therapeutic endeavor. Based on the findings, the therapist will be encouraged either to continue with the original therapeutic approach or, in the case of no change or exacerbation of the problem, to modify or abandon the approach in favor of an alternate one.

4.18.3.2 Psychological Assessment as a Treatment Technique

It is only recently that empirical studies and other articles addressing the therapeutic benefits that can be realized directly from discussing psychological assessment results with the patient have been published. Rather than just providing test feedback as directed by APA's *Ethical principles of psychologists* (APA, 1992), therapeutic use of assessment involves a presentation of assessment results (including assessment materials such as test protocols, profile forms, other assessment summary materials) directly to the patient; an elicitation of the patient's reactions to them; and an in-depth discussion of the meaning of the results in terms of patient-defined assessment goals. In essence, the assessment data can serve as a catalyst for the therapeutic encounter via the objective feedback that is provided to the patient, the patient self-assessment that is stimulated, and the opportunity for patient and therapist to arrive at mutually agreed upon therapeutic goals, based on impressionistic and objective data available to both parties.

4.18.3.3 Psychological Assessment for Outcomes Assessment

Currently, one of the most common reasons for conducting psychological assessment in the USA is to assess the outcomes of behavioral health care treatment. It is difficult to open a trade paper or health care newsletter or to attend a professional conference without being presented with a discussion on either how to "do outcomes" or what the results of a certain facility's outcomes study have revealed. The focus on outcomes assessment most probably can be traced to the "continuous quality improvement" (CQI) movement that was initially implemented in business and industrial settings. The impetus for the movement originally was a desire to produce quality products in the most efficient manner, resulting in increased revenues and decreased costs.

In the health care arena, outcomes assessment has multiple purposes, not the least of which is as a tool for marketing the organization's services. Related to this, those organizations vying for lucrative contracts from third-party payers to provide health care services to their covered lives frequently require outcomes data demonstrating the effectiveness of the services offered by the bidders. Equally important to those awarding contracts is how satisfied patients are with the provider's services. But probably the most important potential use of this data for provider organizations (although not always recognized as such) can be found in the knowledge it yields about what works and what doesn't. In this regard it can serve a program evaluation function. It is this knowledge that, if attended to and acted upon, can lead to improvement in the services the organization offers. When used in this manner, outcomes assessment can become an integral component of the organization's CQI initiative.

But more importantly for the individual patient, outcomes assessment provides a means of objectively measuring how much improvement he or she has made from the time of treatment initiation to the time of treatment termination. Feedback to this effect may serve to instill in the patient greater self-confidence and self-esteem, and/or a more realistic view of where he or she is (from a psychological standpoint) at that particular time in their life. Conversely, it may serve as an objective indicator to the patient of the need for continued treatment.

The purpose of the foregoing is to present a broad overview of psychological assessment as a multipurpose behavioral health care tool. Depending on the individual clinician or provider organization, it may be employed for one or more, or all, of the purposes just described. Knowing the various ways in which psychological assessment can be used in the service of therapeutic change should help the reader understand the more in-depth and detailed discussion about how these applications can facilitate or otherwise add value to the psychotherapeutic services offered by providers. This detailed discussion follows below.

Before beginning this discussion, however, it is important to briefly review the types of instrumentation most likely to be used in therapeutic psychological assessment, as well as the significant considerations and issues related to the selection and use of this instrumentation for the stated purposes. This should further facilitate the reader's understanding of the remainder of the chapter.

4.18.4 GENERAL CONSIDERATIONS FOR THE SELECTION AND USE OF PSYCHOLOGICAL TEST INSTRUMENTATION

New instrumentation for facilitating and evaluating behavioral health care treatment is released by the major test publishers annually. Thus, the availability of instrumentation for these purposes is not an issue. However, selection of the appropriate instrument(s) for one or more of the therapeutic purposes described above is a matter requiring careful consideration. Inattention to the instrument's intended use, its demonstrated psychometric characteristics, its limitations, and other aspects related to its practical application can result in misguided treatment and potentially harmful consequences for a patient.

Several types of instruments could be used for the general therapeutic assessment purposes described above. For example, neuropsychological instruments might be used to assess memory deficits that could impact the clinician's decision to perform further testing, the goals established for treatment, and the approach to treatment that is selected. Tests designed to provide estimates of level of intelligence might be used for the same purposes. It is beyond the scope of this chapter to address, even in the most general way, all of the types of tests, rating scales, and the instrumentation that might be employed in the therapeutic environment. Instead, the focus here will be on general classes of instrumentation that have the greatest applicability in the service of the therapeutic endeavor. To a limited extent, specific examples of such instruments will be presented. This will be followed by a discussion of criteria and considerations that will assist the clinician in selecting the best instrumentation for his or her intended purposes.

4.18.4.1 Types of Instrumentation for Therapeutic Assessment

The instrumentation required for any therapeutic application will depend on: (i) the general purpose(s) for which the assessment is being conducted, and (ii) the level of informational detail that is required for those purpose(s). Generally, one may classify the types of instrumentation that would serve the purpose(s) of the therapeutic assessment into one of four general categories. As mentioned above, other types of instrumentation are frequently used in clinical settings for therapeutic purposes. However, the present discussion will be limited to those more commonly used by a wide variety of clinical psychologists in their day-to-day practices.

4.18.4.1.1 Psychological/psychiatric symptom measures

Probably the most frequently used instrumentation for several therapeutic purposes are measures of psychopathological symptomatology. Besides the fact that these are the types of instruments on which the majority of the clinician's psychological assessment training has probably been focused, they were developed to assess the problems that typically prompt people to seek treatment.

There are several subtypes of these measures of psychological/psychiatric symptomatology. The first is the comprehensive multidimensional measure. This is typically a lengthy, multiscale instrument that measures and provides a graphical profile of the patient on several types of psychopathological symptom domains (e.g., anxiety, depression) or disorders (schizophrenia, antisocial personality). Also, summary indices sometimes are available to provide a more global picture of the individual with regard to his or her psychological status or level of distress. Probably the most widely used and/or recognized of these measures are the Minnesota Multiphasic Personality Inventory (MMPI; Hathaway & McKinley, 1951) and its restandardized revision, the MMPI-2 (Butcher, Dahlstrom, Graham, Tellegen, & Kaemmer, 1989), the Millon Clinical Multiaxial Inventory-III (MCMI-III; Millon, 1994), and the Personality Assessment Inventory (PAI; Morey, 1991).

Multiscale instruments of this type can serve a variety of purposes that facilitate therapeutic efforts. They may be used upon initial contact with the patient to screen for the need for service and, at the same time, yield information that is useful for treatment planning. Indeed, some such instruments (e.g., the MMPI-2) may make available supplementary, content-related, and/or special scales that are designed to assist the user in addressing specific treatment considerations (e.g., low motivation for treatment). Other multiscale instruments might be useful in identifying specific problems that may be unrelated to the patient's chief complaints (e.g., low self-esteem). They can also be administered at numerous times during the course of treatment to monitor the patient's progress toward achieving established goals and to assist in determining what adjustments (if any) must be made to the clinician's approach. In addition, use of the instrument in a pre- and post-treatment fashion provides information related to the outcomes of the treatment. Data obtained in this fashion can be analyzed with results from other patients to evaluate the effectiveness of an individual therapist as well as an organization.

Abbreviated multidimensional measures are quite similar to the comprehensive multidimensional measure in many respects. First, by definition, they contain multiple scales for measuring a variety of symptom domains and/or disorders. They also may allow for the derivation of an index of the patient's general level of psychopathology or distress. In addition, they may be used for screening, treatment planning and monitoring, and outcomes assessment purposes just like the comprehensive instruments. The distinguishing feature of the abbreviated instrument is its length. Again, by definition, these instruments are relatively short, and easy to administer and (usually) score. Their brevity does not allow for an in-depth assessment of the patient and his or her problems, but this is not what these instruments were designed to do.

Probably the most widely used of these brief instruments are Derogatis' family of symptom checklist instruments. These include the original Symptom Checklist-90 (SCL-90; Derogatis, Lipman, & Covi, 1973) and its revision, the

SCL-90-R (Derogatis, 1983). Both of these instruments contain a checklist of 90 psychological symptoms, most of which score on the instruments' nine symptom scales. For each of these instruments an even briefer version has been developed. The first is the Brief Symptom Inventory (BSI; Derogatis, 1992), which was derived from the SCL-90-R. In a health care environment that is cost-conscious and unwilling to make too many demands on patient time, this 53-item instrument is gaining popularity over its longer and more expensive 90-item parent instrument. Similarly, a brief form of the original SCL-90 has been developed. Titled the Symptom Assessment-45 Questionnaire (SA-45; Strategic Advantage, Inc., 1996), its development did not follow Derogatis' approach to the development of the BSI; instead, cluster analytic techniques were used to select five items each for assessing each of the nine symptom domains found on the three Derogatis checklists.

The major strength of the abbreviated multiscale instruments is their ability to broadly and very quickly survey several psychological symptom domains and/or disorders relative to the patient. Its value is most clearly evident in settings where both the time and dollars available for assessment services are quite limited. These instruments provide a lot of information quickly. Because of their brevity, they are much more likely to be completed by patients than their lengthier comprehensive counterparts. This last point is particularly important if one is interested in monitoring treatment or assessing outcomes, both of which require at least two or more assessments to obtain the desired information.

4.18.4.1.2 Measures of general health status and role functioning

During the past decade, there has been an increasing interest in the assessment of health status in health care delivery systems. Initially, this interest was shown mostly by those organizations and settings focusing primarily on the treatment of physical diseases and disorders. Within recent years, behavioral health care providers have recognized the value in assessing the patient's general level of health. It is important to recognize that the term "health" means more than just the absence of disease or debility; it also implies a state of well-being throughout the individual's physical, psychological, and social spheres of existence (World Health Organization [WHO], 1948). Dickey and Wagenaar (1996) point out how this view of health recognizes the importance of eliciting the patient's point of view in assessing health status. They also point to similar conclusions reached by Jahoda (1958) specific to the area of mental health. Here, an individual's self-assessment relative to how he or she feels they should be is an important component of "mental health."

Measures of health status and physical functioning can be classified into one of two groups: generic and condition-specific. Probably the most widely used and respected generic health status measures are the 36-item Medical Outcomes Study Short Form Health Scale (SF-36; Ware & Sherbourne, 1992; Ware, Snow, Kosinski, & Gandek, 1994) and the 39-item Health Status Questionnaire 2.0 (HSQ; Health Outcomes Institute, 1993; Radosevich, Wetzler, & Wilson, 1994). Aside from the minor variations in the scoring of one of the instruments' scales (i.e., Bodily Pain) and the HSQ's inclusion of three depression screening items, the two measures essentially are identical. Each assesses eight dimensions of health, four addressing mental health-related constructs and four addressing physical health-related constructs, that reflect the WHO concept of "health."

Role functioning has recently gained attention as an important variable to address in the course of assessing the impact of a physical or mental disorder on an individual. In devising a treatment plan and monitoring progress over time, it is important to know how the person's ability to work, perform daily tasks, or interact with others is affected by the disorder. The SF-36 and HSQ both address these issues with scales designed for this purpose.

Responding to concerns that even these relatively brief objective measures are too lengthy for regular administration in clinical and research settings, 12-item, abbreviated versions of each have been developed. The SF-12 (Ware, Kosinski, & Keller, 1995) was developed for use in large scale, population-based research where the monitoring of health status at a broad level is all that is required. Also, a 12-item version of the HSQ, the HSQ-12 (Radosevich & Pruitt, 1996), was developed for similar uses. Interestingly, given that the two abbreviated versions were derived from essentially the same instrument, there is only a 50% item overlap between the two shortened instruments. Both instruments are relatively new but the data supporting their use that has been gathered up to 1997 is promising.

Condition-specific health status and functioning measures have been utilized for a number of years. Most have been developed for use with physical rather than mental disorders, diseases, and conditions. However, condition-specific measures of mental health status and functioning are beginning to appear. A major source of this type of instrument is the Minnesota-based Health Outcomes Institute (HOI), a successor to the health care think tank InterStudy. In addition to the HSQ and the HSQ-12, HOI serves as the distributor/clearinghouse for the condition-specific "technology of patient experience (TyPE) specifications." The available TyPEs that would be most useful to clinical psychologists and other behavioral health care practitioners include those developed by a team of researchers at the University of Arkansas Medical Center for use with depressive, phobic, and alcohol and substance disorders. TyPEs for other specific psychological disorders are currently under development at the University of Arkansas for distribution through HOI.

4.18.4.1.3 Quality of life measures

In their brief summary of this area, Andrews, Peters, and Teesson (1994) indicate that most of the definitions of "quality of life" (QOL) describe a multidimensional construct encompassing physical, affective, cognitive, social, and economic domains. Objective measures of QOL focus on environmental resources required to meet one's needs and can be completed by someone other than the patient. The subjective measures of QOL assess the patient's satisfaction with the various aspects of his or her life and thus must be completed by the patient.

Andrews et al. (1994) draw other distinctions in the QOL arena. One has to do with the differences between QOL and health-related quality of life, or HRQL, and (similar to the case with health status measures) the other has to do with the distinction between generic and condition-specific measures of QOL. QOL measures differ from HRQL measures in that the former assess the whole "fabric of life," while the latter assess quality of life as it is affected by a disease or disorder, or by its treatment. Generic measures are designed to assess aspects of life that are generally relevant to most people; condition-specific measures are focused on aspects of the lives of particular disease/disorder populations. However, as Andrews et al. point out, generic and condition-specific QOL measures tend to overlap quite a bit.

4.18.4.1.4 Service satisfaction measures

With the exploding interest in assessing the outcomes of treatment for the patient, it is not surprising to see an accompanying interest in assessing the patient's and, in some instances, the patient's family's satisfaction with the services received. In fact, many professionals and organizations equate satisfaction with outcomes and frequently consider it the most important outcome. In a recent survey of 73 behavioral health care organizations, 71% of the respondents indicated that their outcomes studies included measures of patient satisfaction (Pallak, 1994).

Although some view service satisfaction as an outcome, it is this author's contention that it should not be classified as such. Rather, it should be considered a measure of the overall therapeutic process, encompassing the patient's (and at times, others') view of how the service was delivered, the capabilities and attentiveness of the service provider, the benefits of the service (if any), and any of a number of other selected aspects of the service he or she received. Patient satisfaction surveys don't answer the question "What was the result of the treatment rendered to the patient"; they do answer the question "How did the patient feel about the treatment he or she received?" Thus, they serve an important program evaluation/improvement function.

The number of questionnaires that are currently being used to measure patient satisfaction is countless. This reflects the attempts of individual health care organizations to develop customized measures that assess variables important to their particular needs, which in turn reflects a response to outside demands to "do something" to demonstrate the effectiveness of their services. Often, this "something" has not been evaluated to determine its basic psychometric properties. As a result, there exists numerous options that one may choose from, but very few that actually have demonstrated their validity and reliability as measures of service satisfaction.

Fortunately, there are a few instruments that have been investigated for their psychometric integrity. Probably the most widely used and researched patient satisfaction instrument designed for use in behavioral health care settings is the eight-item version of the Client Satisfaction Questionnaire (CSQ-8; Attkisson & Zwick, 1982; Nguyen, Attkisson, & Stenger, 1983). The CSQ-8 was derived from the original 31-item CSQ (Larsen, Attkisson, Hargreaves, & Nguyen, 1979), which also yielded two longer 18-item alternate forms, the CSQ-18A and CSQ-18B (LeVois, Nguyen, & Attkisson, 1981). The more recent work of Attkisson and his colleagues at the University of California at San Francisco is the Service Satisfaction Scale-30 (SSS-30; Greenfield & Attkisson, 1989), a 30-item multifactorial scale that yields information regarding different aspects of satisfaction with mental health service, such as perceived outcome and manner and skill of the clinician.

4.18.4.2 Guidelines for Instrument Selection

Regardless of the type of instrument one might consider using in the therapeutic environment, many clinical psychologists frequently must choose between many product offerings. But what are the general criteria for the selection of any instrument for psychological assessment? What should guide the clinician's selection of an instrument for a specific therapeutic purpose? As part of their training, clinical psychologists and professionals from related psychological specialties have been educated about the important psychometric properties that should be considered when determining the appropriateness of an instrument for its intended use. However, this is just one of several issues that should be taken into account in an evaluation of a specific instrument for a specific therapeutic use. The guidance that has been offered by experts with regard to instrument selection is worth noting here.

4.18.4.2.1 National Institute of Mental Health criteria

Probably the most thorough and clinically relevant guidelines for the selection of psychological assessment instruments comes from the National Institute of Mental Health (NIMH) supported work of Ciarlo, Brown, Edwards, Kiresuk, and Newman (1986). A synopsis of Newman and Ciarlo's (1994) updated summary of this NIMH work is presented here. Note that the criteria discussed below were originally developed for use in evaluating instruments for outcomes assessment purposes. However, most have relevance to the selection of instrumentation used for the other therapeutic assessment purposes described above. Exceptions and qualifications with regard to this issue will be noted when appropriate.

Newman and Ciarlo (1994) describe 11 criteria for the selection of outcomes assessment instruments, each of which can be grouped into one of five types of consideration. The first consideration is that of applicability. The issue here is the relevance of the instrument to the target population. The instrument should assess those problems, symptoms, characteristics, and so on, that are common to the group to whom the instrument will be administered. The more heterogeneous the population, the more chance that modifications will be required and that these will alter the standardization and psychometric integrity of the instrument. Another applicability issue to consider when the instrument is to be used for outcomes assessment purposes is its independence from the type of treatment to be offered to the population.

The second set of general considerations is that of methods and procedures (Newman & Ciarlo, 1994). Several selection criteria are related to this group. The first is that administration of the instrument is simple and easily taught. Generally, this is more of an issue with clinician-rating scales than self-report scales. In the case of rating scales, concrete examples, or objective referents, at each rating level should be provided to the user. Next, the instrument should allow input not only from the patient but also from other sources (e.g., the clinician, collaterals). The benefits of this include the opportunities to obtain a feel for the patient from many perspectives, to validate reported findings and observations, and to promote honesty in responding from all sources (given that all parties will know that others will also be providing input). The final methods and procedures criterion, though not necessarily as important for the instrument being used for screening or treatment planning purposes, is that the instrument provide information relevant to understanding how the treatment may have effected change in the individual.

Newman and Ciarlo's (1994) third set of considerations have to do with the psychometric strengths of the instruments. According to the NIMH panel of experts, outcomes measures should: (i) meet the minimum psychometric standards for reliability (including internal consistency, test–retest reliability, and as appropriate, interrater reliability) and validity (content, construct, and concurrent validity); (ii) be difficult to “fake bad” or “fake good”; and (iii) be free from response bias and not reactive or sensitive to factors unrelated to the constructs that are being measured (e.g., physical settings, behavior of the treatment staff). These criteria obviously also apply to other psychological instruments used for purposes other than outcomes assessment. However, for outcomes assessment purposes, the instrument also must be sensitive to change related to treatment.

The fourth group of considerations concerns the cost of the instruments. Newman and Ciarlo (1994) point out that the answer to the question of how much one should spend on assessment instrumentation and associated costs (e.g., staff time for administering, scoring, processing, and analyzing the data) will depend on how important the data gathered is to assuring a positive return on the functions they support. In the context of the NIMH undertaking, Newman and Ciarlo felt that the data obtained through treatment outcomes assessment would support screening/treatment planning, efforts in quality assurance and program evaluation, cost containment/utilization review activities, and revenue generation efforts. However, that may be considered the ideal. At this point, the number and nature of the purposes that would be supported by the obtained data will depend on the individual organization. The more purposes the data can serve, the less costly the instrumentation is likely to be, at least from a value standpoint. In terms of actual costs, Ciarlo et al. (1986) estimated that 0.5% of an organization's total budget would be an affordable amount for materials, staff training, data collection, and processing costs related to outcomes assessment. However, one should be mindful that the recommendation was made in 1986 and may not reflect changes in policies, requirements, and attitudes related to the use of psychological assessment instruments since that time.

The final set of considerations in instrument selection has to do with the utility of the instrument. Four criteria related to utility are posited by Newman and Ciarlo (1994). First, the scoring procedures and the manner in which the results are presented should be comprehensible to all with a stake in the treatment of the organization's patients. This would not only include the patient, his or her family, the organization's administrative staff and other treatment staff, but also third-party payers and (in the case of outcomes assessment or program evaluation) legislative and administrative policy makers. Related to this is the criterion that the results of the instrument be easily interpreted by those with a stake in them. Another utility-related criterion is that the instrument should be compatible with a number of clinical practices and theories that are employed in the behavioral health care arena. This should allow for a greater range of test applicability and greater acceptance by the various stakeholders in the patient's treatment.

Another important aspect of utility is that "the instrument support[s] the clinical processes of a service with minimal interference" (Newman & Ciarlo, 1994, p. 107). There are two issues here. The first has to do with whether the instrument can support the screening, planning, and/or monitoring activities in addition to the outcomes assessment activities. In other words, are multiple purposes served by the instrument's results? The second issue is one that has to do with the extent to which the organization's staff is burdened with the collection and processing of assessment data. How much will the assessment process interfere with the daily work flow of the organization's staff? Equally important is whether the benefits that accrue justify the cost of implementing an assessment program for whatever purpose(s).

4.18.4.2.2 Other criteria and considerations

Although the work of Ciarlo and his colleagues provides more extensive instrument selection guidelines than most, others who have addressed the issue have arrived at recommendations that serve to reinforce and/or complement those found in the NIMH document. For example, Gavin Andrews' work in Australia has led to significant contributions to the body of outcomes assessment knowledge. As part of this, Andrews et al. (1994) have identified six general "qualities of consumer outcome measures" that are generally in concordance with those from the NIMH study. First, the measure should meet the criterion of applicability. In other words,

> it should address dimensions which are important to the consumer (symptoms, disability, and consumer satisfaction) and useful for the clinician in formulating and conducting treatment, yet the measure should be one which can have its data aggregated in a meaningful way so that the requirements of management can be addressed. (p. 30)

Multidimensional instruments yielding a profile of scores on all dimensions of interest are viewed as a means of best serving the interests of all concerned.

Acceptability, that is, being both brief and user-friendly, is another desirable quality identified by Andrews et al (1994). Closely associated with this is the criterion of practicality. It might be viewed as a composite of those NIMH criteria related to matters of cost, ease of scoring and interpretation, and training in the use and interpretation of the measure. Again in agreement with the NIMH work, the final three criteria identified by Andrews et al. relate to reliability, validity, and sensitivity to change. With regard to reliability, Andrews et al. specify what they consider to be the minimum levels of acceptable internal consistency reliability (0.90 for long tests), interrater reliability (0.40), and construct and criterion validity (0.50). They also stress the importance of an instrument's face validity in helping to ensure cooperation from the patient, and of self-report instruments having multiple response options (rather then just "yes/no" options) for increasing sensitivity of an instrument to small but relevant changes in the patient's status over time.

In Ficken's (1995) discussion of the role of assessment in an MCO environment, he concludes that the difficulties clinicians are experiencing in demonstrating the utility of psychological assessment to payers lies in the fact the instruments and objectives of traditional psychological assessment are not in synch with the needs of MCOs. The solution to the problem appears simple:

> the underlying objectives of testing must be aligned with the values and processes of MCOs. In short, this means identifying decision points in managed care processes that could be improved with objective, standardized data. There are two avenues in which these can be pursued: through facilitation/objectification of clinical-decision processes and through outcome assessment. (p. 12)

In general, Ficken (1995) sees opportunities in areas that this author has previously identified as screening, treatment planning, and outcomes assessment, specifically in the areas of primary medical care and behavioral health care (see below). Requirements of instruments used for screening were noted to include:

(i) high levels of sensitivity and specificity to diagnostic criteria from the *Diagnostic and statistical manual of mental disorders* (4th ed., *DSM-IV*; American Psychiatric Association, 1994) or the most up-to-date version of the *International classification of diseases* (*ICD*);

(ii) a focus on hard-to-detect (in a single office visit) but treatable disorders that are associated with imminent harm to self or others, significant suffering, and a decrease in productivity;

(iii) an administration time of no more than 10 minutes; and

(iv) an administration protocol that easily integrates into the organization's work flow.

Cases testing "positive" on the screener would be administered one or more "second-tier" instrument(s) to establish severity and a specific diagnosis. Ficken feels that if they are to be accepted by MCOs, these second-tier instruments should meet the requirements of screeners and either specify or rule out a diagnosis.

According to Ficken (1995), successful outcomes assessment instruments also must possess certain qualities. Because the areas most important to assess for outcomes measurement purposes are symptom reduction, level of functioning, quality of life and patient satisfaction, the instrument should (i) focus on one of these areas, (ii) be brief, (iii) meet "traditional standards" for validity and reliability, and (iv) be sensitive to clinical change.

Based on the work of Vermillion and Pfeiffer (1993), Burlingame, Lambert, Reisinger, Neff, and Mosier (1995) recommended four criteria for the selection of outcomes measures. The first is acceptable "technical features," that is, validity and reliability. Specifically, these authors recommended that instruments have an internal consistency of at least 0.80, test–retest reliability of at least 0.70, and concurrent validity of at least 0.50. The second criterion is "practicality features." These include brevity, ease of administration and scoring, and simplicity of the reporting of results. Third, the instrumentation should be "suitable" for the patients that are seen within the setting. Thus, because of the nature of most presenting problems in mental health settings, it should assess symptomatology and psychosocial functioning. The fourth criterion is sensitivity to "meaningful" change over time, allowing for a differentiation of *symptomatic* change from interpersonal/social role *functional* change.

Schlosser (1995) proposed a rather nontraditional view of "outcomes assessment." In what he refers to as a "patient-centric" view, assessment information is gathered and used during the course of therapy to bring about change during therapy, not after therapy has ended. Essentially, this equates to what this author has referred to above (and discusses in more detail below) as treatment monitoring. In this model, Schlosser feels that this type of assessment requires "elements regarding very specific, theoretically derived, empirically validated areas of functioning" (Schlosser, 1995, p. 66). These would involve the use of both illness and well-being measures that assess the patient on emotional, mental/cognitive, physical, social, life direction, and life satisfaction dimensions.

Many of Schlosser's (1995) considerations for selection of such measures are not unique (i.e., having "acceptable' levels of reliability and validity, brief, low-cost, and sensitive). However, for the purposes described Schlosser also indicates that they should also: (i) have "paradigmatic sensibility" (i.e., key words have the same meaning across instruments); (ii) be designed for repeated administration for feedback or self-monitoring purposes; and (iii) provide actionable information.

In addition to some already mentioned criteria (acceptable validity, reliability, affordability, ease of administration, and ease of data entry and analysis), Sederer et al. (1996) discuss other considerations that warrant attention in selecting outcomes measures for specific situations. These include automation capabilities related to availability of software for data analysis and reporting, compatibility with the organization's existing information system, and the ability to enter data via an optical scanner. They also provide advice that should help guide the user in selecting the appropriate instrumentation:

> A plan should be developed that addresses the following questions: which patients will be included in the study? What outcomes will be most

> effected by the treatment? When will the outcomes be measured? Who is going to read (and use) the information provided by the outcomes study? The more specific the answer to these questions, the better the choice of outcome instrument. (p. 4)

This and other recommendations would appear equally applicable when selecting instruments for other therapeutic assessment purposes.

One final set of criteria should be considered in the light of the following section on screening. Screening for the likelihood of the presence of disorders or for the need for additional assessment requires considerations that do not necessarily apply to instruments when they are used for the other therapeutic assessment purposes addressed in this chapter. A major one here is a specific consideration relative to a screener's criterion validity. Although broadly encompassed by the construct of "validity" that was previously discussed, it demands particular attention when evaluating instruments for screening purposes. What is being referred to here is the instrument's classification accuracy or efficiency.

Classification efficiency is usually expressed in terms of the following statistics: *sensitivity*, that is, the proportion of those individuals with the characteristic of interest who are accurately identified as such; *specificity*, that is, the proportion of individuals not having the characteristic of interest who are accurately identified as such); *positive predictive power*, which is the proportion of a population identified by the instrument as having the characteristic who actually do have the characteristic, and *negative predictive power*, which is the proportion of a population identified by the instrument as not having the characteristic who actually do not have the characteristic. This information can provide the clinical psychologist and other evaluators with empirically based information that is useful in the type of decision-making requiring the selection of one of two choices. The questions answered are typically those of the "yes/no" type, such as "Is the patient depressed or not?" or "Does the patient have a psychological problem significant enough to require treatment?" The reader is referred to Baldessarini, Finkelstein, and Arana (1983) for a discussion of issues related to the use of these statistics.

In evaluating these statistics, one must consider a few very important issues. One is the degree to which the clinician is willing to accept false-positives or false-negatives. This will be a function of the importance of maximizing the correct identification of those with the particular characteristic of interest vs. the importance of maximizing the correct identification of those not having the characteristic vs. the importance of optimizing the identification of both groups. This in turn will be dependent on the cutoff score recommended by the developer of the instrument and/or the efficiency values that are available when other cutoff scores are applied. These and related issues are discussed more extensively in the next section.

4.18.5 PSYCHOLOGICAL ASSESSMENT AS A TOOL FOR SCREENING

One of the most significant ways in which psychological assessment can contribute to the development of an economic and efficient behavioral health care delivery system is by using it to screen potential patients for need for behavioral health care services, and/or to determine the likelihood that the problem being screened is a particular disorder of interest. Probably the most concise, informative treatment of the topic of the use of psychological tests in screening for behavioral health care disorders is provided by Derogatis and DellaPietra (1994). In this work, these authors turn to the Commission on Chronic Illness (1987) to provide a good working definition of health care screening in general, that being:

> the presumptive identification of unrecognized disease or defect by the application of tests, examinations or other procedures which can be applied rapidly to sort out apparently well persons who probably have a disease from those who probably do not. (Commission on Chronic Illness, 1987, p. 45)

Derogatis and DellaPietra (1994) further clarify the nature and the use of screening procedures, stating that:

> the screening process represents a relatively unrefined sieve that is designed to segregate the cohort under assessment into "positives" who presumptively have the condition, and "negatives" who are ostensibly free of the disorder. Screening is not a diagnostic procedure *per se*. Rather, it represents a preliminary filtering operation that identifies those individuals with the highest probability of having the disorder in question for subsequent specific diagnostic evaluation. Individuals found negative by the screening process are not evaluated further. (p. 23)

The most important aspect of any screening procedure is the efficiency with which it can provide information useful to clinical decision-making. In the area of clinical psychology, the most efficient and thoroughly investigated screening procedures involve the use of psychological assessment instruments. As implied by the foregoing, the power or utility of a psychological screener lies in its ability to determine, with a high level of probability, whether the respondent does or does not have a particular disorder or condition, or whether he or she is or is not a member of a group with clearly defined characteristics. In daily clinical practice, the most commonly used screeners are those designed specifically to identify some aspect of psychological functioning or disturbance or provide a broad overview of the respondent's point-in-time mental status. Examples of problem-specific screeners include the Beck Depression Inventory (BDI; Beck, Rush, Shaw, & Emery, 1979) and the State–Trait Anxiety Inventory (STAI; Spielberger, 1983). Examples of screeners for more generalized psychopathology or distress include the SA-45 and BSI.

4.18.5.1 Research-based Use of Psychological Screeners

The establishment of a system for screening for a particular disorder or condition involves determining what it is one wants to screen in or screen out, at what level of probability one feels comfortable in making that decision, and how many incorrect classifications or what percentage of errors one is willing to tolerate. Once it is decided what one wishes to screen for, one then must turn to the instrument's classification efficiency statistics, that is, sensitivity, specificity, positive predictive power (PPP), and negative predictive power (NPP), for the information necessary to determine whether a given instrument is suitable for the intended purpose(s).

Recall that sensitivity refers to the proportion of those with the characteristic of interest who are accurately identified as such by an instrument or procedure, while specificity refers to the proportion of those not having the characteristic of interest who are accurately identified. The cutoff score, index value, or other criterion used for classification can be adjusted to maximize either sensitivity or specificity. However, maximization of one will necessarily result in a decrease in the other, thus increasing the percentage of false-positives (with maximized sensitivity) or false-negatives (with maximized specificity). Stated differently, false-positives will increase as specificity decreases, while false-negatives will increase as sensitivity decreases (Elwood, 1993).

Another approach is to optimize both sensitivity and specificity, thus yielding a fairly even balance of true positives and true negatives. Although optimization might seem to be the preferable approach in all instances, there are situations in which a maximization approach is more desirable. For example, a psychiatric hospital with an inordinately high rate of inpatient suicide attempts begins to employ a screener designed to help identify patients with suicide potential as part of its admission procedures. The hospital adjusts the classification cutoff score to a level that identifies all suicidal patients in the screener's normative group. This cutoff score is then applied to all patients being admitted to the hospital for the purpose of identifying those requiring an extensive evaluation for suicide potential. This not only increases the number of true positives, but it also decreases the specificity and increases the number of false positives. However, the trade-off of identifying more suicidal patients early on with having more nonsuicidal patients receiving suicide evaluations would appear worthwhile for the hospital's purposes. Similarly, in other instances, maximization of specificity may be the preferred approach. For example, an MCO might wish to use a measure of overall level of psychological distress to identify those covered lives that are not in need of behavioral health care services. Sensitivity will decrease but, for the MCO's purposes, this might be quite acceptable.

Hsiao, Bartko, and Potter (1989) note that "a diagnostic test will not have a unique sensitivity and specificity. Instead, for each diagnostic test, the relationship between sensitivity and specificity depends on the cutoff point chosen for the test" (p. 665). The effect of employing individual classification cutoff points can be presented via the use of receiver operating characteristic (ROC) curves. These curves are nothing more than a plotting of the resulting true positive rate (sensitivity) against the false positive rate for each cutoff score that might be employed with a test used for classification purposes. The plotting allows for a graphical representation of what may be gained and/or lost by shifting cutoff scores. The resulting area underneath the curve provides an indication of how well the test performs. Development of ROC curves from available data for a test being considered for screening purposes is recommended. The reader is referred to Hsiao et al. and Metz (1978) for a more detailed discussion of ROC curves and their use.

In day-to-day clinical work, an instrument's PPP and NPP can provide information that is more useful than sensitivity and specificity. As Elwood (1993) has pointed out,

> Although sensitivity and specificity do provide important information about the overall performance of a test, their limitation in classifying

> individual subjects becomes evident when they are considered in terms of conditional probabilities. Sensitivity is $P\ (+/d)$, the probability (P) of a positive test result (+) given that the subject has the target disorder (d). However, the task of the clinicians in assessing individual patients is just the opposite: determining $P\ (d/+)$, the probability that a patient has the disorder given that he or she obtained an abnormal test score. In the same way, specificity expresses $P\ (-/-d)$, the probability that a patient will have a negative test result given that he or she does not have the disorder. Here again, the task confronting the clinician is usually just the opposite: determining $P\ (-d/-)$, the probability that the patient does not have the disorder given a negative test result. (p. 410)

A note of caution is warranted when evaluating the two predictive powers of a test. Unlike sensitivity and specificity, both PPP and NPP are affected and change according to the prevalence or base rate at which the condition or characteristic of interest (i.e., that which is being screened by the test) occurs within a given setting. As Elwood (1993) reports, the lowering of base rates results in lower PPPs while increasing base rates result in higher PPPs. The opposite trend is true for NPPs. He notes that this is an important consideration because clinical tests are frequently validated using samples in which the prevalence rate is 0.50, or 50%. Thus, it is not surprising to see a test's PPP drop in "real-life" applications where the prevalence is lower.

Derogatis and DellaPietra (1994) indicate that a procedure referred to as "sequential screening" may provide at least a partial solution to the limitations or other problems that low base rates may pose for the predictive powers of an instrument. Sequential screening essentially involves the administration of two screeners, each of which measures the condition of interest, and two-phase screening. In the first phase, one screener is administered to the low base rate population. The purpose of this is to identify those individuals without the condition, thus requiring relatively good specificity. These individuals are eliminated from involvement in the second phase, resulting in an increase in the prevalence of the condition among those who remain. This group is then administered another screener of equal or better sensitivity. With the increased prevalence of the condition in the remaining group, the false positive rate will be much lower. As Derogatis and DellaPietra point out,

> Sequential screening essentially zeros in on a high-risk subgroup of the population of interest by virtue of a series of consecutive sieves. These have the effect of eliminating from consideration individuals with low likelihood of having the disorder, and simultaneously raising the base rate of the condition in the remaining sample. (p. 45)

In summary, PPP and NPP can provide information that is quite valuable to those making important clinical decisions, such as determining need for behavioral health care services, assigning diagnoses, or determining appropriate level of care. However, these users must be cognizant of the manner in which the predictive powers may change with the population to which the test or procedure is applied.

4.18.5.2 Implementation of Screeners into the Daily Work Flow of Service Delivery

The utility of a screening instrument is only as good as the degree to which it can be integrated into an organization's daily regimen of service delivery. This, in turn, depends on a number of factors. The first is the degree to which the administration and scoring of the screener is quick and easy, and the amount of time required to train the provider's staff to successfully incorporate the screener into their day-to-day activities.

The second factor relates to its use. Here, the screener is not used for anything other than determining the likelihood that the patient does or does not have the specific condition or characteristic the instrument is designed to assess. Use for any other purpose (e.g., assigning a diagnosis based solely on screener results, determining the likelihood of the presence of other characteristics) only serves to undermine the integrity of the instrument in the eyes of staff, payers, and other parties with a vested interest in the screening process.

The third factor has to do with the ability of the provider to act on the information. It must be clear how the clinician should proceed based on the information available.

The final factor is staff acceptance and commitment to the screening process. This comes only with a clear understanding of the importance of the screening, the usefulness of the obtained information, and how the screening process is to be incorporated into the organization's business flow.

Ficken (1995) provides an example of how screeners can be integrated into an assessment system designed to assist primary care physicians to identify patients with psychiatric disorders. This system (which also allows for the incorporation of practice guidelines) seems to take into account the first three utility-related factors listed above. It begins with the administration of a screener that is highly sensitive and specific to *DSM*- or *ICD*-related disorders. Ficken indicates that screeners should require no more than 10 minutes to complete, and that "their administration must be integrated seamlessly into the standard clinical routine" (p. 13). Somewhat similarly to the sequence described by Derogatis and DellaPietra (1994), positive findings would lead to a second level of testing. Here, another screener that meets the same requirements as those for the first screener and also affirms or rules out a diagnosis would be administered. Positive findings would lead to additional assessment for treatment planning purposes. Consistent with standard practice, Ficken recommends confirmation of screener findings by a qualified psychologist or physician.

4.18.6 PSYCHOLOGICAL ASSESSMENT AS A TOOL FOR TREATMENT PLANNING

The administration of screeners is only one way in which psychological assessment can serve as a valuable tool for treatment planning. However, many would argue that it is the most limited way in which this tool can be used for planning a course of treatment. When employed by a trained clinician, psychological assessment can provide information that can greatly facilitate and enhance the planning of the therapeutic intervention for the individual patient.

The importance of treatment planning has received significant attention during recent years. The reasons for this were summarized previously by this author (Maruish, 1990) as follows:

> Among important and interrelated reasons ... [are] concerted efforts to make psychotherapy more efficient and cost effective, the growing influence of "third parties" (insurance companies and the federal government) that are called upon to foot the bill for psychological as well as medical treatments, and society's disenchantment with open-ended forms of psychotherapy without clearly defined goals. (p. iii)

The role that psychological assessment can play in planning a course of treatment for behavioral health care problems is significant. Butcher (1990) indicated that information available from instruments such as the MMPI-2 can not only assist in identifying problems (see above) and establishing communication with the patient (see below), it can also help ensure that the plan for treatment is consistent with the patient's personality and external resources. In addition, psychological assessment may reveal potential obstacles to therapy, areas of potential growth, and problems of which the patient may not be consciously aware. Moreover, both Butcher and Appelbaum (1990) viewed testing as a means of quickly obtaining a second opinion. Other benefits of the results of psychological assessment, identified by Appelbaum, include assistance in identifying patient strengths and weaknesses, identification of the complexity of the patient's personality, and establishment of a reference point or guide to refer to during the therapeutic episode.

The types of information that can be derived from patient assessment and the manner in which it is applied for this purpose are quite varied—a fact that will become evident below. Nevertheless, Strupp (see Butcher, 1990) probably provided the best summary of the potential contribution of psychological assessment to treatment planning, stating that "careful assessment of patient's personality resources and liabilities is of inestimable importance. It will predictably save money and avoid misplaced therapeutic effort; it can also enhance the likelihood of favorable treatment outcomes for suitable patients" (pp. v–vi).

4.18.6.1 Assumptions About Treatment Planning

The introduction to this section presented a broad overview of ways in which psychological assessment can assist in devising and successfully implementing plans of treatment for behavioral health care patients. These and other benefits will be discussed in greater detail below. However, it is important to first clarify what treatment planning is and some of the general, implicit assumptions that one typically can make about this important therapeutic activity.

For the purpose of this discussion, the term "treatment planning" indicates that part of a therapeutic episode in which the treatment provider develops a set of goals for an individual presenting with behavioral health care problems, and outlines the specific means by which he/she or other resources will assist the patient in achieving those goals in the most efficient manner. General assumptions underlying the treatment planning process are as follows.

(i) The patient is experiencing behavioral health problems that have been identified either by themself or by another party. Common external sources of problem identification include the patient's spouse, parent, teacher, employer, and the legal system.

(ii) The patient experiences some degree of internal and/or external motivation to eliminate or reduce the identified problems. An example of external motivation to change is the potential loss of job or marriage if problems are not resolved.

(iii) The goals of treatment are tied either directly or indirectly to the identified problems.

(iv) The goals of treatment have definable criteria for achievement, are indeed achievable by the patient, and are developed in collaboration with the patient.

(v) The prioritization of goals is reflected in the treatment plan.

(vi) The patient's progress toward achievement of the treatment goals can be tracked and compared against an expected path of improvement in either a formal or informal manner. This expected path of improvement may be based on the clinician's experience or (ideally) on objective data gathered on patients similar to the patient.

(vii) Deviations from the expected path of improvement will lead to a modification in the treatment plan, followed by subsequent monitoring to determine the effectiveness of the alteration.

These assumptions should not be considered exhaustive, nor are they reflective of what actually occurs in all situations. For example, some patients seen for therapeutic services may have no motivation to change. As may be seen in juvenile detention settings or in cases where children are brought to treatment by the parents, their participation in treatment is forced, and they may engage in intentional efforts to sabotage any therapeutic intervention. Also, it is likely that there are still clinicians who identify and prioritize treatment goals without the direct input of the patient. Nevertheless, the assumptions above represent this author's view of the aspects of treatment planning that have a direct bearing on the manner in which psychological assessment can best serve treatment planning efforts.

4.18.6.2 The Benefits of Psychological Assessment for Treatment Planning

As has already been touched upon, there are several ways in which psychological assessment can assist in the planning of treatment for behavioral health care patients. Following is a discussion of the more common and evident contributions that assessment can make to treatment planning efforts. These can be organized into four general categories: problem identification, problem clarification, identification of important patient characteristics, and monitoring of treatment progress.

4.18.6.2.1 Problem identification

Probably the most common use of psychological assessment in the service of treatment planning is for the purpose of problem identification. Often, the use of psychological testing *per se* is not needed to identify what problems the patient is experiencing. He or she will either tell the clinician directly without questioning, or they will readily admit to their problem(s) during the course of a clinical interview. However, this is not always the case.

The value of psychological testing becomes apparent in those cases where the patient is hesitant or unable to identify the nature of his or her problems. However, with a motivated and engaged patient who responds to items on a well validated and reliable test in an open and honest manner, the process of identifying what brought the patient to treatment also may be greatly facilitated. Cooperation shown during testing may be attributable to the nonthreatening nature of responding to questions presented on paper or a computer monitor (as opposed to those posed by another human being); the subtle, indirect, or otherwise nonthreatening nature of the questions (compared to those asked by the clinician); instrumentation that "casts a wider net" than the clinician in his or her interview with the patient; or any combination of these reasons.

In addition, the nature of some of the more commonly used psychological test instruments allows for the identification of secondary problems of significant severity that might otherwise be overlooked. Multidimensional inventories such as the MMPI-2 and the PAI are good examples of these types of instruments. Moreover, these instruments may be sensitive to other problems or patient traits or characteristics that may not necessarily be problems but which may exacerbate or otherwise contribute to the maintenance of the patient's problems.

Note that the type of problem identification described here is different from that conducted during screening (see above). Whereas screening is focused on determining the presence or absence of a single problem, problem identification generally takes a broader view and investigates the possibility of the presence of multiple problem areas. At the same time, there is also an attempt to determine the extent to which the problem area(s) affect the patient's ability to function.

4.18.6.2.2 Problem clarification

Psychological testing can often assist in the clarification of a known problem. Through tests designed for use with individuals presenting problems similar to the patient's, aspects of identified problems can be elucidated. This will improve the patient's and clinician's understanding of the problem and likely lead to a better treatment plan. The three most important types of information that can be gleaned for this purpose are the severity of the problems, the complexity of the problems, and the degree to which the problems impair the patient's ability to function in one or more life roles.

The manner in which a patient is treated depends a great deal on the severity of his or her problem. In particular, severity has a great bearing on the setting in which the behavioral health care intervention is provided. Those whose problems are so severe that they are considered a danger to themselves or others more often than not are best suited for inpatient treatment, at least until dangerousness is no longer an issue. Similarly, problem severity may be a primary criterion for an evaluation for a medication adjunct to treatment. Severity also may have a bearing on the type of psychotherapeutic approach that is taken by the clinician. For example, it may be more productive for the clinician to take a supportive role with severe cases; all things being equal, a more confrontational approach may be more appropriate with patients with problems in the mild to moderate range of severity.

As alluded to above, the problems of patients seeking behavioral health care services are frequently multidimensional. Patient and environmental factors that play into the formation and maintenance of a problem, along with the latter's relationship with other problems, all contribute to its complexity. Knowing the complexity of the target problems is invaluable in devising an effective treatment plan. Again, multidimensional instruments or batteries of tests measuring specific aspects of psychological dysfunction serve this purpose well.

As with problem severity, knowledge of the complexity of a patient's psychological problems can help the clinician and patient in many aspects of treatment planning, including determination of appropriate setting, therapeutic approach, need for medication, and other matters on which important decisions must be made. However, possibly of equal importance and concern to the patient and outside parties (spouse, employer, school, etc.) is the extent to which these problems affect the patient's ability to function in his or her role as parent, child, employee, student, friend, and so on. Data gathered from the administration of measures of role functioning can provide information that not only clarifies the impact of the patient's problems and serves to establish role-specific goals, but also identifies other parties that may serve as potential allies in the therapeutic process. In general, the most important role-functioning domains for assessment would be those related to work or school performance, interpersonal relationships, and activities of daily living (ADLs).

4.18.6.2.3 Identification of important patient characteristics

The identification and clarification of the patient's problems is of key importance in planning a course of treatment for the patient. However, there are numerous types of nonproblem-oriented patient information that can be useful in planning treatment and can be rather easily identified through the use of psychological assessment instruments. The vast majority of treatment plans are developed or modified with consideration of at least some of these other patient characteristics. The exceptions mostly are found with clinicians or programs that take a "one size fits all" approach to the treatment of general or specific types of disorders. It is beyond the scope of this chapter to provide an exhaustive list of what other types of information may be available to the clinician. However, a few are particularly worth mentioning.

Probably the most useful type of nonproblem-oriented information that can be gleaned from psychological assessment results is the identification of the patient characteristics or conditions that can serve as assets or areas of strength for the patient in working toward achieving the therapeutic goals. For example, Morey and Henry (1994) point to the utility of the PAI's Nonsupport scale in identifying whether the patient perceives an adequate social support network, this being a predictor of positive therapeutic progress. Other examples include "normal" personality characteristic information, such as that which can be obtained from Gough, McClosky, and Meehl's Dominance and Social Responsibility scales (1951, 1952) developed for use with the MMPI/MMPI-2. Greene (1991) indicates that those with high scores on the Dominance scale are described as "being able to take charge of responsibility for their lives. They are poised, self-assured, and confident of their own abilities" (p. 209). Gough and his colleagues interpreted high scores on the Social Responsibility scale as being indicative of individuals who, among other things, trust the world, are self-assured and poised, and stress the need for one to carry his or her share of duties. Thus, scores on these scales may reveal some important aspects of patient functioning that can be used in the service of affecting therapeutic change.

Similarly, knowledge of the patient's weaknesses or deficits may impact the type of treatment plan that is devised. Greene and Clopton (1994) provided numerous types of deficit-relevant information from the MMPI-2 Content Scales that have implications for treatment planning. For example, a clinically significant score ($T > 64$) on the Anger scale should lead one to consider the inclusion of training in assertiveness and/or anger control as part of the patient's treatment. On the other hand, uneasiness in social situations, as suggested by a significantly elevated score on either the Low Self-Esteem or Social Discomfort scale, suggests that a supportive approach to the intervention would be beneficial, at least initially.

Moreover, use of specially designed scales and procedures can provide information related to the patient's ability to become engaged in the therapeutic process. For example, the MMPI-2 Negative Treatment Indicators content scale developed by Butcher and his colleagues (Butcher, Graham, Williams, & Ben-Porath, 1989) may be useful in determining whether the patient is likely to be resistant to any form of "talk" therapy. Morey and Henry (1994) have supplied algorithms utilizing T scores for various PAI scales to make statements about the presence of positive characteristics, such as the presence of sufficient distress to motivate engagement in treatment, the ability to form a therapeutic alliance, and the capacity to utilize psychotherapy. The Therapeutic Reactance Scale (Dowd, Milne, & Wise, 1991) is yet another example of an instrument from which the clinician can be forewarned of potential resistance to therapeutic intervention.

Other types of patient characteristics that can be identified through psychological assessment have implications for the choice of the therapeutic approach and thus can contribute significantly to the treatment planning process. Beutler and his colleagues (Beutler & Clarkin, 1990; Beutler, Wakefield, & Williams, 1994; Beutler & Williams, 1995) have identified four patient characteristics that are thought to be important to matching patients and treatment approach for maximized therapeutic effectiveness. These include symptom severity, symptom complexity, coping style, and potential resistance to treatment. At different points in time, other patient variables also have been identified by these investigators as important considerations in the selection of the best treatment for a given patient. These include the problem-solving phase the patient has reached (Beutler & Clarkin, 1990), and subjective distress and social support (L.E. Beutler, personal communication, January 15, 1996).

Moreland (1996) points out how psychological assessment can assist in determining whether the patient deals with problems through internalizing or externalizing behaviors. All things being equal, internalizers would probably profit most from an insight-oriented approach rather than a behaviorally oriented approach. The reverse would be true for externalizers. In addition, cognitive factors also are important. Knowing that intelligence test results indicate an average or above IQ can assist the clinician in determining whether a patient will be able to benefit from a cognitive approach.

4.18.6.2.4 Monitoring of progress along the path of expected improvement

Information from repeated testing during the treatment process can help the clinician to determine if the treatment plan is appropriate for the patient at that particular point in time. Thus, many clinicians use psychological assessment to determine whether their patients are showing the expected improvement as treatment progresses. If not, adjustments can be made. These adjustments may reflect the need for a more intensive or aggressive treatment approach (e.g., increased number of psychotherapeutic sessions each week, addition of a medication adjunct) or for a less intensive approach (e.g., reduce or terminate medication, transfer from inpatient to outpatient care). Either way, this may require further retesting in order to determine whether the treatment revisions have impacted the course of change in the expected direction. This process may be repeated any number of times. In-treatment retestings also can provide information relevant to the decision of when to terminate treatment.

The goal of monitoring is to determine whether treatment is "on track" with the progress that is expected at a given point in time. When and how often one might assess the patient is dependent on a few factors. The first is the instrumentation. Many instruments are designed to assess the patient's status at the time of testing. Items on these measures are generally worded in the present tense (e.g., "I feel tense and nervous," "I feel that my family loves and cares about me"). Changes from one day to the next on the constructs measured by the instrument should be reflected in the test results.

Other instruments, however, ask the patient to indicate if a variable of interest has been present, or how much or to what extent it has occurred during a specific time period in the past. The items usually are asked in the context of something like "During the past month, how often have you . . ." or "During the past week, to what extent has ...” Readministration of a measure containing interval-of-time-specific items or subsets of items should be undertaken only after a period of time equivalent to or longer than the time interval to be considered in responding to the items has past. For example, an instrument which asks the patient to consider how much certain symptoms have been problematic during the past seven days should not be readministered for at least seven days. The responses elicited during a readministration that occurs less than seven days after the first administration would include the patient’s consideration of his or her status during the previously considered time period. This may make interpretation of the change of symptom status (if any) from the first to the second assessment difficult if not impossible.

Methods to determine whether clinically significant change has occurred from one point in time to another have been developed and can be used for treatment monitoring purposes. These are discussed in the outcomes assessment section of this chapter below. However, for monitoring purposes, another approach to evaluating therapeutic change may be superior. This approach may be referred to as the “glide path” approach, with the term referring to the narrow descent course or path that airplanes must follow when landing. Deviation from the flight glide path requires corrections in the plane’s speed, altitude, and/or attitude in order to return to the glide path and a safe landing.

R.L. Kane (personal communication, July 22, 1996) has indicated that just as a pilot has the instrumentation to alert him or her about the plane’s position on the glide path, the clinician may use psychological assessment instruments to track how well the patient is following the glide path of treatment. The glide path in this case represents expected improvement over time in one or more measurable areas of functioning (e.g., symptom severity, social role functioning, occupational performance). The expectations would be based on objective data obtained from similar patients at various points during their treatment and would allow for minor deviations from the path. The end of the glide path is one or more specific goals that are part of the treatment plan. Thus, “arrival” at the end of the glide path signifies the attainment of specific treatment goals.

4.18.7 PSYCHOLOGICAL ASSESSMENT AS A THERAPEUTIC INTERVENTION

The use of psychological assessment as a means of therapeutic intervention in and of itself has received more than passing attention during the past few years. “Therapeutic assessment” with the MMPI-2 has received particular attention primarily through the work of Finn and his associates (Finn, 1996a, 1996b; Finn & Martin, in press; Finn & Tonsager, 1992). Finn’s approach appears to be applicable with instruments or batteries of instruments that provide multidimensional information relevant to the concerns of patients seeking answers to questions related to their mental health status. The approach espoused by Finn thus will be presented here as a model for deriving direct therapeutic benefits from the psychological assessment experience.

4.18.7.1 What Is Therapeutic Assessment?

In discussing the use of the MMPI-2 as a therapeutic intervention, Finn (1996a) describes an assessment procedure whose goal is to “gather accurate information about clients ... and then use this information to help clients understand themselves and make positive changes in their lives” (p. 3). Elaborating on this procedure and extending it to the use of any test, Finn and Martin (in press) describe therapeutic assessment as

> collaborative, interpersonal, focused, time limited, and flexible. It is ... very interactive and requires the greatest of clinical skills in a challenging role for the clinician. It is unsurpassed in a respectfulness for clients: collaborating with them to address *their* concerns (around which the work revolves), acknowledging them as experts on themselves and recognizing their contributions as essential, and providing to them usable answers to their questions in a therapeutic manner.

The ultimate goal of therapeutic assessment is to provide an experience for the client that will allow him/her to take steps toward greater psychological health and a more fulfilling life. This is done by recognizing the client’s characteristic ways of being, understanding in a meaningful, idiographic way the problems the client faces, providing a safe environment for the client to explore change, and providing the opportunity for the client to experience new ways of being in a supportive environment.

Simply stated, therapeutic assessment may be considered an approach to the assessment of mental health patients in which the patient is not only the primary provider of information needed to answer questions, but also is actively involved in formulating the questions that are to be answered by the assessment. Feedback regarding the results of the assessment is provided to the patient and is considered a primary, and possibly the principal element of the assessment process. Thus, the patient becomes a partner in the assessment process; as a result, therapeutic and other benefits accrue.

The reader should note that in this section, the term "therapeutic assessment" is used to denote the specific approach advocated by Finn and his colleagues for using the psychological assessment process as an opportunity for therapeutic intervention. It should not be confused with the more general term "therapeutic psychological assessment" as it has been employed throughout this chapter; "therapeutic assessment" is but one aspect of therapeutic psychological assessment.

4.18.7.2 The Impetus for Therapeutic Assessment

To say that clinical psychologists performing psychological assessments in mental health settings traditionally have never shared much of their findings with their patients is probably not an overstatement. A common scenario throughout many mental health settings was that a patient being treated by a psychologist was evaluated by the latter, or a patient was referred to the psychologist by another mental health professional for assessment only. In the first instance, the degree to which the psychologist might directly share the results of the often lengthy and expensive evaluation would vary. Generally, a detailed review of the findings would be a rarity. In the latter instance, the patient would be evaluated, a report of the results dictated, and a copy of the report sent back to the referring clinician. In either instance, the purpose of the assessment probably would be to answer questions posed by the treating clinician. Unfortunately, the patient and his or her concerns as they related to the psychological assessment were typically of only secondary consideration, if any.

Fortunately, recent occurrences have begun to change the way in which assessment information is used. Consequently, the degree to which the patient is involved in the assessment process is changing. One reason for this is the relatively recent revision of the ethical standards of the APA (1992). This revision included a mandate for psychologists to provide feedback to clients whom they test. According to ethical standard 2.09:

> Unless the nature of the relationship is clearly explained to the person being assessed in advance and precludes provision of an explanation of results (such as in some organizational consulting, preemployment or security screenings, and forensic evaluations), psychologists ensure that an explanation of the results is provided using language that is reasonably understandable to the person assessed or to another legally authorized person on behalf of the client. Regardless of whether the scoring and interpretation are done by the psychologist, by assistants, or by automated or other outside services, psychologists take reasonable steps to ensure that appropriate explanations of results are given. (p. 8)

Many clinicians and other psychologists involved in assessment activities (e.g., counseling psychologists, neuropsychologists) have had to modify their practice routine to accommodate this requirement. Some view this requirement as resulting in an improvement in the quality of their services; others likely see it as nothing more than an inconvenience which, in the era of managed care and limited access to treatment, further limits the amount of time they have to work with a patient. However, most would agree that the patient has benefited from the required feedback.

Finn and Tonsager (1992) identified other factors that may have contributed to the recent interest in providing patients with assessment feedback. One is another external influence, that is, the recognition of the patient's right to see their medical and psychiatric health care records. However, they also point to several clinically and research-based findings and impressions that suggest that therapeutic assessment enhances patient care through the facilitation of patient–therapist rapport, cooperation during the assessment process, positive feelings about the process and the clinician, improvement in mental health status, and feelings of being understood by another. In addition, Finn and Tonsager refer to Finn and Butcher's (1991) summary of potential benefits that may accrue from providing test results feedback. The listed benefits, based on clinical experience, include increased feelings of self-esteem and hope, reduced symptomatology and feelings of isolation, increased understanding and self-awareness, and increased motivation to seek or be more actively involved in mental health treatment. Finally, Finn and Martin (in press) note that the therapeutic assessment process can lead to increased feelings of mastery and control and decreased feelings of alienation. At the same time, it can serve as a model for relationships that can result in mutual respect and the patient being seen for who he or she is.

4.18.7.3 The Therapeutic Assessment Process

Finn (1996a) has outlined a three-step procedure for therapeutic assessment using the MMPI-2. As indicated above, it should work equally well with other multidimensional instruments that one might select. Finn describes this procedure as one to be used in those situations in which the patient is seen only for assessment (i.e., the patient is not to be treated later by the assessing clinician). From the present author's standpoint, the procedures are equally applicable for use by clinicians who test patients whom they later treat. With these points in mind, the three-step procedure is summarized below.

4.18.7.3.1 Step 1: The initial interview

According to Finn (1996a), the initial interview with the patient serves multiple purposes. It provides an opportunity to build rapport, or to increase rapport if a patient–therapist relationship already exists. The assessment task is presented as a collaborative one, and the patient is given the opportunity to identify questions that he or she would like answered using the assessment data. Background information related to the patient-identified questions is subsequently gathered. Any reservations about participating in the therapeutic assessment process (e.g., confidentiality, previous negative experiences with assessment) are dealt with in order to facilitate maximal involvement in the process.

After responding to the patient's concerns, Finn (1996a) recommends that the clinician restate the questions posed earlier by the patient. This ensures the accuracy of what the patient would like to have addressed by the assessment. The patient also is encouraged to ask questions of the clinician, thus reinforcing the collaborative context or atmosphere that the clinician is trying to establish. Step 1 is completed as the instrumentation and its administration, as well as the responsibilities and expectations of each party, are clearly defined and the particulars of the process (e.g., date and time of assessment, date and time of the feedback session, clinician fees) are discussed and agreed upon.

4.18.7.3.2 Step 2: Preparing for the feedback session

Upon completion of the administration and scoring of the instrumentation used during the assessment, the clinician first outlines all results obtained from the assessment, including those not directly related to the patient's previously stated questions. Finn (1996a) presents a well-organized outline for the types of information that the trained user can extract from MMPI-2 data. These include response consistency, test-taking attitude, distress and disturbance, major symptoms, underlying personality, behavior in relationships, implications for treatment, diagnostic impression, and recommendations. Unfortunately, clinicians who do not or cannot use the MMPI-2 or other well-researched, multidimensional instruments will not have the same amount or type of data available to them. (This should not preclude them from identifying the types of valid and useful information that can be derived from the instruments and organizing it into a usable form for presentation to the patient.) This is followed by a determination of how to present the results to the patient. This can be guided by the clinician asking himself or herself the following questions:

> (i) How do the (test) findings relate to the client's goals?
> (ii) What are the most important findings of the (tests administered)?
> (iii) To what extent is the client likely to already know about and agree with the (test) findings?
> (iv) How much new information is the client likely to be able to integrate in the feedback session?
> (v) What is likely to happen if the client becomes overwhelmed or is presented with findings that are greatly discrepant from his/her current self-concept? (p. 34)

As a final point in this step, Finn (1996a) indicates that the clinician must determine what is the best way to present the information to the patient so that he or she can accept and integrate the information while maintaining his or her sense of identity and self-esteem. This also is a time when the clinician can identify information that he or she may not wish to reveal to the patient because it is not important to answering the patient's questions; doing so may negatively affect the collaborative relationship. In addition, the clinician may want to prepare for presenting those aspects of feedback that he or she feels will be most problematic for him or her (i.e., the clinician) by role-playing with a colleague.

4.18.7.3.3 Step 3: The feedback session

As Finn (1996a) states: "The overriding goal of feedback sessions is to have a therapeutic interaction with clients" (p. 44). Thus, the initial tasks of the feedback session are focused on setting the stage for this type of encounter. This is accomplished by allaying any anxiety the patient may have about the session, reaffirming the collaborative relationship, and familiarizing him or her with the presentation of the test results (e.g., explaining the profile sheet upon which the results are graphed, discussing the normative group to which he or she will be compared, providing an explanation of standard scores).

When the session preparation is completed, the clinician begins providing feedback to the patient (Finn, 1996a). This, of course, is centered on answering the questions posed by the patient during Step 1. Beginning with a positive finding from the assessment, the clinician proceeds to first address those questions that the patient is most likely to accept. He or she then carefully moves to the findings that are more likely to be anxiety-arousing for the patient and/or challenge his or her self-concept. A key element to this step is to have the patient verify the accuracy of each finding and provide a real-life example of the interpretation that is offered. Alternately, one should ask the patient to modify the interpretation to make it more in line with how he or she sees themselves and their situation. Finn (1996a) provides specific suggestions about how to deal with a rejection of a finding, the final suggestion being to allow the client to disagree with but not totally dismiss the finding. This leaves the door open for representing the finding at another time when the patient is more open to accepting it.

Finn (1996a) recommends that the clinician should end the session by responding to any additional questions the patient may have; confirming that the patient has accurately understood the information that was presented; giving permission for the patient to contact the clinician should further questions arise; and (in the assessment-only arrangement) termination of the relationship. Throughout the session, the clinician maintains a supportive stance with regard to any affective reactions to the findings.

4.18.7.3.4 Additional steps

Finn and Martin (in press) indicate two additional steps that may be added to the therapeutic assessment process. The purpose of the first additional step, referred to as an "assessment intervention session" essentially is to clarify initial test findings through the administration of additional instruments. For example, Finn and Martin explain how MMPI-2 findings can be further fleshed out through a nonstandard administration of an instrument such as the Thematic Apperception Test (TAT). Here, the clinician controls the patient's interpretation in order to draw out information relevant to the patient's questions. Also, solutions to problems elicited by the TAT cards are suggested to the patient.

The other additional step discussed by Finn and Martin (in press) is the provision of a written report of the findings to the patient. In addition to summarizing both the test results and the answers to the patient's questions, it also attempts to elicit feedback and reactions from the patient about the assessment.

The reader should note that the preceding summary presents only the key technical aspects of the therapeutic assessment procedures espoused by Finn and his associates. Much of the clinical/dynamic aspect of this approach has not been addressed because of the focus of this chapter. Those interested in incorporating the process into their clinical practice are encouraged to read Finn (1996a).

4.18.7.4 Empirical Support for Therapeutic Assessment

Noting the lack of direct empirical support for the therapeutic effects of sharing test results with patients, Finn and Tonsager (1992) investigated the benefits of providing feedback to university counseling center clients regarding their MMPI-2 results. A total of 32 subjects underwent therapeutic assessment and feedback procedures similar to those described above while on the counseling center's waiting list. Another 28 subjects were recruited from the same waiting list to serve as a control group. There were no significant differences between the two groups on any important demographic or examiner contact-interval variables.

Instead of receiving feedback, Finn and Tonsager's (1992) control group received nontherapeutic attention from the examiner. However, they were administered the same dependent measures as the feedback group at the same time as the experimental group received feedback. They also were administered the same dependent measures as the experimental group two weeks later (i.e., two weeks after the experimental group received the feedback) in order to determine if there were differences between the two groups on those dependent measures. These measures included a self-esteem questionnaire, a symptom checklist (i.e., the SCL-90-R), a measure of private and public self-consciousness, and a questionnaire assessing the subjects' subjective impressions of the feedback session. (Note that the control group was administered only that portion of the feedback assessment questionnaire that was relevant to them.)

The results of Finn and Tonsager's (1992) study indicated that compared to the control group, the feedback group demonstrated significantly less distress at the two-week post-feedback follow up, and significantly higher levels of self-esteem and hope at both the time of feedback and the two-week post-feedback follow up. In other findings, feelings about the feedback sessions were positively and significantly correlated with changes in self-esteem from testing to feedback, both from feedback to follow up and from testing to follow up among those who were administered the MMPI-2. In addition, the change in level of distress from feedback to follow up correlated significantly with private self-consciousness (i.e., the tendency to focus on the internal aspects of oneself) but not with public self-consciousness.

4.18.8 PSYCHOLOGICAL ASSESSMENT AS A TOOL FOR OUTCOMES MANAGEMENT

The 1990s have witnessed a positively accelerating growth curve reflecting the level of interest in and development of behavioral health care outcomes programs. Cagney and Woods (1994) attribute this to four major factors. First, behavioral health care purchasers are asking for information regarding the value of the services they buy. Second, there is an increasing number of purchasers who are requiring a demonstration of patient improvement and satisfaction. Third, MCOs need data that demonstrate that their providers render efficient and effective services. And fourth, outcomes information will be needed for the "quality report cards" that MCOs anticipate they will be required to provide in the future. In short, fueled by soaring health care costs, there has been an increasing need for providers to demonstrate that what they do is effective. And all of this has occurred within the context of the continuous quality improvement (CQI) movement, in which there have been similar trends in the level of interest and growth.

As this author has noted previously, the interest in and necessity for outcomes measurement in the era of managed care and accountability provides a unique opportunity for clinical psychologists to use their training and skills in assessment (Maruish, 1994). However, the extent to which the clinical psychologist becomes a key and successful contributor to an organization's outcomes initiative (whatever that might be) will depend on his or her understanding of what "outcomes" and their measurement and applications are all about.

4.18.8.1 What Are Outcomes?

Before discussing outcomes, it is important to have a clear understanding of what is meant by the term. Experience has shown that the meaning varies according to whom one may speak.

Donabedian (1985) has identified three dimensions of quality of care. "Structure" refers to the organization providing the care. It includes aspects such as how the organization is "organized," the physical facilities and equipment, and the number and professional qualifications of its staff. "Process" refers to the specific types of services that are provided to a given patient (or group of patients) during a specific episode of care. These might include various types of tests and assessments (e.g., psychological tests, lab tests, magnetic resonance imaging), therapeutic interventions (e.g., group psychotherapy, medication), and discharge planning activities. Treatment complications (e.g., drug reactions) are also included here. "Outcomes", on the other hand, refers to the results of the specific treatment that was rendered.

The outcomes, or results, of treatment should not refer to change in only a single aspect of functioning. Treatment may impact various facets of a patient's life. Stewart and Ware (1992) have identified five broad aspects of general health status: physical health, mental health, social functioning, role functioning, and general health perception. Treatment may affect these aspects of health in different ways, depending on the disease or disorder being treated and the effectiveness of the treatment. Some specific aspects of functioning related to these five areas of general health status that are commonly measured include: feeling of well-being, psychological symptom status, use of alcohol and other drugs, functioning on the job or at school, marital/family relationships, utilization of health care services, and ability to cope.

In considering the various types of outcomes that might be assessed in behavioral health care settings, a substantial number of clinicians probably would identify symptomatic change in psychological status as being the most important. Nevertheless, however important change in symptom status may have been in the past, clinical psychologists and other behavioral health care providers have come to realize that changes in many of the other aspects of functioning identified by Stewart and Ware (1992) are equally important indicators of treatment effectiveness. As Sederer et al. (1996) have noted:

> Outcome for patients, families, employers, and payers is not simply confined to symptomatic change. Equally important to those affected by the care rendered is the patient's capacity to function within a family, community, or work environment or to exist independently, without undue burden to the family and social welfare

> system. Also important is the patient's ability to show improvement in any concurrent medical and psychiatric disorder ... Finally, not only do patients seek symptomatic improvement, but they want to experience a subjective sense of health and well being. (p. 2)

A much broader perspective is offered in Faulker and Gray's *The 1995 behavioral outcomes and guidelines sourcebook* (Migdail, Youngs, & Bengen-Seltzer, 1995):

> Outcomes measures are being redefined from a vague "is the patient doing better?" to more specific questions, such as, "Does treatment work in ways that are measurably valuable to the patient in terms of daily functioning level and satisfaction, to the payor in terms of value for each dollar spent, to the managed care organization charged with administering the purchaser's dollars, and to the clinician charged with demonstrating value for hours spent?" (p. 1)

Thus, "outcomes" holds a different meaning for each of the different parties who have a stake in behavioral health care delivery. What is measured generally depends on the purposes for which outcomes assessment is undertaken. As will be shown, these vary greatly.

4.18.8.2 Outcomes Assessment: Measurement, Monitoring, and Management

Just as it is important to be clear about what is meant by outcomes, it is equally important to clarify the three general purposes for which outcomes assessment may be employed. The first is outcomes measurement. This involves nothing more than pre- and post-treatment assessment of one or more variables to determine the amount of change that has occurred (if any) in these variables as a result of therapeutic intervention.

A more useful approach is that of outcomes monitoring. This refers to "the use of periodic assessment of treatment outcomes to permit inferences about what has produced change" (Dorwart, 1996, p. 46). Like treatment progress monitoring used for treatment planning purposes, outcomes monitoring involves the tracking of changes in the status of one or more outcomes variables at multiple points in time. Assuming a baseline assessment at the beginning of treatment, reassessment may occur one or more times during the course of treatment (e.g., weekly, monthly), at the time of termination, and/or during one or more periods of post-termination follow up. Whereas treatment progress monitoring is used to determine how much the patient is on or off the expected course of improvement, outcomes monitoring focuses on revealing aspects about the therapeutic process that seem to affect change.

The third and most useful purpose of outcomes assessment is that of outcomes management. Dorwart (1996) defines outcomes management as "the use of monitoring information in the management of patients to improve both the clinical and administrative processes for delivering care" (pp. 46–47). In outcomes management, information is used to improve the quality of services offered to the patient population(s) served by the provider, not to any one patient. Information gained through the assessment of patients can provide the organization with indications of what works best with whom and under what set of circumstances, thus helping to improve the quality of services for all patients. In essence, outcomes management can serve as a tool for those organizations with an interest in implementing a CQI initiative.

4.18.8.3 The Benefits of Outcomes Assessment

The implementation of any type of outcomes assessment initiative within an organization does not come without effort from and cost to the organization. However, if it is implemented properly, all interested parties, that is, patients, clinicians, provider organizations, payers, and the health care industry as a whole, should find a substantial yield from the outlay of time and money. Cagney and Woods (1994) identify several benefits to patients, including enhanced health and quality of life, improved health care quality, and effective use of the dollars paid into benefits plans. For providers, the outcomes data can result in improved clinical skills, information related to the quality of care provided and local practice standards, increased profitability, and decreased concerns over possible litigation.

Outside of the clinical context, benefits also can accrue to payers and MCOs. Cagney and Woods (1994) see the potential payer benefits as including healthier workers, improved health care quality and worker productivity, and reduced or contained health care costs. As for MCOs, the benefits include increased profits, information that can help shape the practice patterns of their providers, and decisions that are based on quality of care.

4.18.8.4 The Therapeutic Use of Outcomes Assessment

The foregoing overview of outcomes assessment provides the background necessary for discussing the use of psychological outcomes assessment data in day-to-day clinical practice.

Whereas the focus of the above review was centered on both the individual patient and patient populations, it now will narrow to the use of outcomes assessment primarily in service to the individual patient. The reader interested in issues related to large, organization-wide outcomes studies conducted for outcomes management purposes (as defined above) is encouraged to seek other sources of information that specifically address that topic (see, for example, Migdail, Youngs, & Bengden-Seltzer, 1995; Newman, 1994).

There is no one system or approach to the assessment of treatment outcomes for an individual patient that is appropriate for all providers of behavioral health care services. Because of the specific type of outcomes one is interested in, the reasons for assessing them, and the manner in which they may impact the decisions made by the patient, payer and clinician, any successful and useful outcomes assessment approach must be customized. Customization should reflect the needs of the primary beneficiary of the information gained from the assessment (i.e., patient, payer, or provider), with consideration of the secondary stakeholders in the therapeutic endeavor. Ideally, the identified primary beneficiary would be the patient. Although this is not always the case, it would appear that only rarely would the patient not benefit, at least indirectly, from the gathering of outcomes data.

Following are considerations and recommendations for the development and implementation of an outcomes assessment initiative by behavioral health care providers. Although space limitations do not allow a comprehensive review of all issues and solutions, the information that follows can be useful to clinical psychologists and others with similar training wishing to begin to incorporate outcomes assessment into their standard therapeutic routine.

4.18.8.4.1 Purpose of the outcomes assessment

There are numerous reasons for assessing outcomes. For example, in a recent survey of 73 behavioral health care organizations, various reasons were identified by the participants as to why they had conducted outcomes studies (Pallak, 1994). Among the several indicated, the top five reasons (in descending order) were to: evaluate outcomes for patients, evaluate provider effectiveness, evaluate integrated treatment programs, manage individual patients, and support sales and marketing efforts. However, from the clinician's standpoint, a couple of purposes are worth noting.

In addition to monitoring the course of progress during treatment (see above), clinicians may employ outcomes assessment to obtain a direct measure of how much patient improvement has occurred as the result of the course of treatment intervention. Here, the findings are of more benefit to the clinician than to the patient himself because a pre- and post-treatment approach to the assessment is utilized. The information will not lead to any change in the patient providing the information, but the feedback it provides to the clinician could assist him in the treatment of other patients later on.

Another common reason for outcomes assessment is to demonstrate the patient's need for therapeutic services beyond that which is typically covered by the patient's medical and behavioral health care benefits. When assessment is conducted for this reason, the patient and clinician are only secondary beneficiaries of the outcomes data. As will be shown below, the type of information that a third party payer requires for authorization of extended benefits may not be the most relevant or useful to the patient or the clinician.

4.18.8.4.2 What to measure

The aspects or dimensions of patient functioning that are measured as part of outcomes assessment will depend on the purpose for which the assessment is being conducted. As discussed earlier, probably the most commonly measured variable is that of symptomatology or psychological/mental health status. After all, disturbance or disruption in this dimension is probably the most common reason why people seek behavioral health care services in the first place. However, there are other reasons for seeking help, including difficulties in coping with various types of life transitions (e.g., a new job, recent marriage or divorce, other changes in the work or home environment), inability to deal with the behavior of others (e.g., spouse, children), general dissatisfaction with life, or perhaps other less common reasons. Additional assessment of related variables therefore may be necessary, or may even take precedence over the assessment of symptoms or other mental health indicators.

In the vast majority of the cases seen for behavioral health care services, the assessment of the patient's overall level of psychological distress or disturbance will yield the most singularly useful information, regardless of whether it is used for outcomes measurement, outcomes monitoring, outcomes management, or to meet the requirements of third-party payers for authorization of additional benefits. Indices such as the Positive Symptom Total (PST) or Global Severity Index (GSI) that are part of the SA-45 or BSI can provide this type of information efficiently and economically.

For some patients, measures of one or more specific psychological disorders or symptom clusters are at least as important if not more important than overall symptom or mental health status. Here, if interest is in only one disorder or symptom cluster (e.g., depression), one may choose to measure only that particular set of symptoms using an instrument designed specifically for that purpose (e.g., use of the BDI with depressed patients). For those interested in assessing the outcomes of treatment relative to multiple psychological dimensions, the administration of more than one disorder-specific instrument or a single, multidimensional instrument which assesses all or most of the dimensions of interest would be required. Again, instruments such as the SA-45 or the BSI can provide a quick, broad assessment of multiple symptom domains. Although much lengthier, other multiscale instruments, such as the MMPI-2 or the PAI, permit a more detailed assessment of several disorders or symptom domains using one inventory.

In many cases, the assessment of mental health status is adequate for outcomes assessment purposes. There are other instances in which changes in psychological distress or disturbance either provide only a partial indication of the degree to which therapeutic intervention has been successful, are not of interest to the patient or a third-party payer, are unrelated to the reason why the patient sought services in the first place, or are otherwise inadequate or unacceptable as measures of improvement in the patient's condition. One may find that for some patients, improved functioning on the job, at school, or with family or friends is much more relevant and important than symptom reduction. For other patients, improvement in their quality of life or feeling of well-being is more meaningful.

It is not always a simple matter to determine exactly what should be measured. However, careful consideration of the following questions should greatly facilitate the decision.

(i) *Why did the patient seek services?* People pursue treatment for many reasons. The patient's stated reason for seeking therapeutic assistance may be the first clue in determining what is important to measure.

(ii) *What did the patient hope to gain from treatment?* The patient's stated goals for the treatment he or she is about to receive may be a primary consideration in the selection of outcomes to be assessed.

(iii) *What are the patient's criteria for the successful completion of the current therapeutic episode?* The patient's goals for treatment may provide only a broad target for the therapeutic intervention. Having the patient identify exactly what will have to happen to consider treatment successful and no longer needed will help in specifying the most important constructs and/or behaviors to assess.

(iv) *What are the clinician's criteria for the successful completion of the current therapeutic episode?* What the patient identifies as being important to accomplish during treatment may reflect a lack of insight into his or her problems, or it might not otherwise concur with what the clinician's experience would indicate.

(v) *What are the criteria of significant third parties for the successful completion of the current therapeutic episode?* From a strict treatment perspective, this should be given the least amount of consideration. From a more realistic perspective, one cannot overlook the expectations and limitations that one or more third parties have for the treatment that is rendered. The expectations and limitations set by the patient's behavioral health care plan, the guidelines of the organization in which the clinician practices, and possibly other external forces may significantly play into the decision about when to terminate treatment.

(vi) *What, if any, are the outcomes initiatives within the provider organization?* One cannot ignore any outcomes programs that have been initiated by the organization in which the therapeutic services are delivered. Regardless of the problems and goals of the individual patient, organization-wide studies of effectiveness may dictate the gathering of specific types of outcomes data from patients who have received services.

Note that the selection of the variables to be assessed may address more than one of the above issues. Ideally, this is what should happen. However, one needs to take care that the gathering of outcomes data does not become too burdensome. As a general rule, the more outcomes data one attempts to gather from a given patient or collateral, the less likely one is to obtain any data at all. The key is to identify the point at which the amount of data that can be obtained from a patient and/or collaterals, and the ease with which it can be gathered, is optimized.

4.18.8.4.3 How to measure

Once the decision concerning what to measure has been made, one must then decide how this should be measured. In many cases, the most important data will be that obtained directly from the patient through the use of self-report instruments. Underlying this assertion are the assumptions that valid and reliable instrumentation, appropriate to the needs of the patient, is available to the clinician; the patient can read at the level required by the instruments; and the patient is motivated to respond honestly to the questions asked. If this is not the case, other options are available.

Other types of data-gathering tools may be substituted for self-report measures. Rating scales completed by the clinician or other members of the treatment staff may provide information that is as useful as that elicited directly from the patient. In those cases in which the patient is severely disturbed, unable to give valid and reliable answers (e.g., younger children), unable to read, or is an otherwise inappropriate candidate for a self-report measure, clinical rating scales can substitute as useful means of gathering data. Related to these instruments are parent-completed inventories for child and adolescent patients. These are particularly useful in obtaining information about the child or teen's behavior that might not otherwise be known.

Collateral rating instruments can also be used to gather information in addition to that obtained from self-report measures. When used in this manner, these instruments provide a mechanism by which the clinician and other treatment staff can contribute data to the outcomes assessment endeavor. This not only results in the clinician or provider organization having more information upon which to evaluate the outcomes of therapeutic intervention, it also gives the clinician an opportunity to ensure that the perspective of the treatment provider is considered in the evaluation of the effects of the treatment given.

Another potential source of outcomes information is administrative data. In many of the larger provider organizations, this information is easily retrieved through their management information systems (MISs). Data related to the patient's diagnosis, dose and regimen of medication, physical findings, course of treatment, and other types of data typically stored in these systems can be useful to those evaluating the outcomes of therapeutic intervention.

4.18.8.4.4 When to measure

There are no hard and fast rules, guidelines, or accepted conventions related to when outcomes should be assessed. The common practice is to assess the patient at least at treatment initiation and treatment termination/discharge. Obviously, at the time of treatment initiation, the clinician should obtain a baseline measure of whatever variables will be measured at the termination. At the minimum, this allows for "outcomes measurement" as described above. As has been discussed, additional assessment of the patient on the variables of interest can take place at other points in time, that is, at other times during the course of treatment and upon post-discharge follow up.

Many would argue that postdischarge/post-termination follow-up assessment provides the best or most important indication of the outcomes of therapeutic intervention. Two types of comparisons may be made on follow-up. The first is a comparison of the patient's status on the variables of interest at the time of treatment initiation, or at the time of discharge or termination, to that of the patient at some point after treatment has ended. Either way, this follow-up data will provide an indication of the more lasting effects of the intervention. Generally, the variables of interest for this type of comparison include such things as symptom presence and intensity, feeling of well-being, frequency of substance use, and social and role functioning.

The second type of post-treatment investigation involves looking at the frequency at which some aspect(s) of the patient's life circumstances, behavior or functioning occurred during a given period prior to treatment, compared to that which occurred during an equivalent period of time immediately preceding the post-discharge assessment. This approach is commonly used in determining the cost-offset benefits of treatment. For example, the number of times a patient has been seen in an emergency room for psychiatric problems during the three-month period preceding the initiation of outpatient treatment can be compared to the number of emergency room visits during the three-month period preceding the postdischarge follow-up assessment. Not only can this provide an indication of the degree to which treatment has helped the patient deal with his problems, it can also demonstrate how much medical expenses have been reduced through the patient's decreased use of costly emergency room services.

In general, post-discharge outcomes assessment probably should take place no sooner than a month after treatment has ended. When feasible, one probably should wait three to six months to assess the variables. This should provide a more valid indication of the lasting effects of treatment. Assessments being conducted to determine the frequency with which some behavior or event occurs (as may be needed to determine cost-offset benefits) can be accomplished no sooner than the reference time interval used in the baseline assessment. Thus, suppose that the patient reports 10 emergency room visits during the three-month period prior to treatment. If one wants to know if the patient's emergency room visits have decreased after treatment, the assessment cannot take place any earlier than three months after treatment termination.

4.18.8.4.5 How to analyze outcomes data

There are two general approaches to the analysis of treatment outcomes data. The first is to determine whether changes in patient scores on outcomes measures are statistically significant. The other is to establish whether these changes are clinically significant. Use of standard tests of statistical significance is important in the analysis of group or population change data. Clinical significance is more relevant to change in the individual patient. As this chapter is focused on the individual patient, this section will center on matters related to determining clinically significant change as the result of treatment.

The issue of clinical significance has received a great deal of attention in psychotherapy research during the past several years. This is at least partially owing to the work of Jacobson and his colleagues (Jacobson, Follette, & Revenstorf, 1984, 1986; Jacobson & Truax, 1991) and others (e.g., Christensen & Mendoza, 1986; Speer, 1992; Wampold & Jenson, 1986). Their work came at a time when researchers began to recognize that traditional statistical comparisons do not reveal a great deal about the efficacy of therapy. In discussing the topic, Jacobson and Truax broadly define the clinical significance of a treatment as

> its ability to meet standards of efficacy set by consumers, clinicians, and researchers. While there is little consensus in the field regarding what these standards should be, various criteria have been suggested: a high percentage of clients improving...; a level of change that is recognizable by peers and significant others ...; an elimination of the presenting problem ...; normative levels of functioning at the end of therapy ... ; high end-state functioning at the end of therapy ...; or changes that significantly reduce one's risk for various health problems. (p. 12)

From their perspective, Jacobson and his colleagues (Jacobson, Follette, & Revenstorf, 1984; Jacobson & Truax, 1991) felt that clinically significant change could be conceptualized in one of three ways. Thus, for clinically significant change to have occurred, the measured level of functioning following the therapeutic episode would either:

(i) fall outside the range of the dysfunctional population by at least two standard deviations away from the mean of that population, in the direction of functionality;

(ii) fall within two standard deviations of the mean for the normal or functional population; or

(iii) be closer to the mean of the functional population than to that of the dysfunctional population.

Jacobson and Truax viewed the third option as being the least arbitrary and provided different recommendations for determining cutoffs for clinically significant change, depending upon the availability of normative data. Lambert (1994) demonstrated how the third option could be modified to allow for the inclusion of more than one categorization of dysfunction (e.g., mild, moderate, severe). This assumes, of course, that the necessary normative data needed to separate the gradations of dysfunction are available.

At the same time, these same investigators noted the importance of considering the change in the measured variables of interest from pre- to post-treatment, in addition to the patient's functional status at the end of therapy. To this end, Jacobson et al. (1984) proposed the concomitant use of a reliable change (RC) index to determine whether change is clinically significant. This index, modified on the recommendation of Christensen and Mendoza (1986), is nothing more than the pretest score minus the posttest score divided by the standard error of the difference of the two scores, expressed as:

$$\mathrm{RC} = (x_2 - x_1)/S_{\mathrm{diff}}$$

where x_1 is the pretest score, x_2 is the post-test score, and S_{diff} is the standard error of the difference. The standard error of the difference is computed as:

$$S_{\mathrm{diff}} = \sqrt{2\,(\mathrm{SEM})^2}$$

where SEM is the standard error of measurement for a functional group (e.g., normals, nonpatients) on the instrument. If the RC index is greater than 1.96, the change in scores is not likely to be due to chance ($p < 0.05$), but rather to reflect real change.

Speer (1992) recommended a different approach when regression to the mean has been demonstrated to contribute to the improvement in scores from pre- to post-test. The alternate approach, based on the combined work of Nunnally (1967) and Edwards, Yarvis, Mueller, Zingale, and Wagman (1978), involves developing a confidence interval of ± 2 SEMs around the estimated true pretest score. A post-test score falling outside of this confidence interval is considered significantly different from the initial pretest score at $p < 0.05$. Using this approach, more change is needed to show clinically significant improvement than to show clinically significant deterioration. Note that the criterion for determining whether regression to the mean is occurring is met when a negative correlation is found to exist between the pretreatment score and amount of change that has taken place. This implies the evaluation of group data, and for this reason this empirical criterion may not be of use for the individual patient unless the latter is a member of a sample for which test results are available.

Lambert (1994) proposes a modified recommendation for the dual criteria for clinically significant change (that is, RC greater than 1.96 and movement of the patient's score from the dysfunctional group's distribution to the functional group's distribution) such that movement from one degree of dysfunction to a lesser degree would also meet one of the two criteria for clinically significant change. In an example, Lambert illustrated that normative data for the Global Severity Index (GSI) found in the SCL-90-R literature can be used to empirically define four levels of symptom intensity: asymptomatic, mildly symptomatic, moderately symptomatic, and severely symptomatic. Assuming an RC of 1.96 or greater, clinically significant change can be said to have occurred if a patient's GSI score moves from severely to moderately or mildly symptomatic, or to asymptomatic; from moderately to mildly symptomatic, or to asymptomatic; or from mildly symptomatic to asymptomatic. Although this criterion is less stringent than having to move from being symptomatic (regardless of the severity) to asymptomatic, it still provides information that is quite useful for clinical decision making.

4.18.9 FUTURE DIRECTIONS

The ways in which clinical psychologists have conducted the types of psychological assessment described in this chapter have undergone dramatic changes during the 1990s. This should come as no surprise to anyone who spends a few minutes a day skimming the newspaper or watching television. The health care revolution started gaining momentum at the beginning of the 1990s and has not since slowed down. And there are no indications that it will subside in the foreseeable future. There was no real reason to think that behavioral health care would be spared from being a target of the revolution, and there is no good reason why it should have been spared. The behavioral health care industry certainly had contributed its share of waste, inefficiency, and lack of accountability to the problems that led to the revolution. Now, like other areas of health care, it is forced to "clean up its act." Some consumers of mental health or chemical dependency services have benefited from the revolution, others have not. In any case, the way in which health care is delivered and financed has changed, and clinical psychologists and other behavioral health care professionals must adapt to survive in the market.

Some of those involved in the delivery of psychological assessment services may wonder (with some fear and trepidation) where the revolution is leading the behavioral health care industry and, in particular, how their ability to practice will be affected. At the same time, others are eagerly awaiting the inevitable advances in technology and other resources that come with the passage of time. What will occur is open to speculation. However, close observation of the practice of psychological assessment and the various industries that support it (particularly the forms of therapeutic assessment described in this chapter) has led this author to arrive at some predictions as to where the field of therapeutic psychological assessment is headed and the implications these have for clinicians, provider organizations, and patients. What follows in this section are the most important of these predictions. Also included are what this author feels are the needs that must be met if psychological assessment is to continue to be a valued contributor to the delivery of efficient, cost-effective behavioral health care.

4.18.9.1 What the Industry Is Moving Away From?

One way of discussing what the field is moving toward is to first talk about what it is moving away from. In the case of therapeutic psychological assessment, two trends are becoming quite clear. First, starting at the beginning of this last decade of the twentieth century, the use of (and reimbursement for) psychological assessment has gradually been curtailed. This particularly has been the case with regard to indiscriminate assessment involving the administration of lengthy and expensive batteries of psychological tests. Payers began to demand evidence that the knowledge gained from the administration of these instruments contributed to the delivery of cost-effective, efficient care to mental health and substance abuse patients. There are no indications that this trend will stop.

Second, assessment has begun to move away from the use of lengthy, multidimensional objective instruments (e.g., the MMPI) or time-consuming projective techniques (e.g., Rorschach) that previously represented the standard of practice. When assessment is authorized now, it usually involves the use of inexpensive yet well-validated, problem-oriented instruments. This reflects modern behavioral health care's time-limited, problem-oriented approach to treatment. The clinician can no longer afford to spend a great deal of time in assessment activities when the patient has only a limited number of payer-authorized sessions with him or her. Thus, both now and in the foreseeable future, brief instruments will be used for problem identification or clarification, progress monitoring, and/or outcomes assessment.

4.18.9.2 Trends in Instrumentation

The move toward the use of brief, problem-oriented instruments for therapeutic psychological assessment purposes has just been identified. Another trend in the selection of instrumentation is the increasing use of public domain tests, questionnaires, rating scales, and other types of measurement tools. Previously, these free-use instruments were not developed with the rigor that is usually applied in the development of psychometrically sound instruments by commercial test publishers. Consequently, they typically lacked the validity and reliability data that are necessary to judge their psychometric integrity.

Recently, however, there has been a significant improvement in the quality and documentation of the public domain and other "for-free" tests that are available for therapeutic psychological assessment. Instruments such as the SF-36/SF-12 and HSQ/HSQ-12 health measures are good examples of such tools. These and instruments such as the Behavior and Symptom Identification Scale (BASIS-32; Eisen, Grob, & Klein, 1986) and the Outcome Questionnaire (OQ-45.1; Lambert, Lunnen, Umphress, Hansen, & Burlingame, 1994) have undergone psychometric scrutiny and have gained widespread acceptance. Although copyrighted, they may be used for a nominal one-time or annual licensing fee; thus, they generally are treated much like public domain assessment tools. One can expect that other quality, useful instruments will be made available for use at little or no cost in the future.

As for the types of instrumentation that will be needed and developed, one can probably expect some changes. Accompanying the increasing focus on outcomes assessment is a recognition by payers and patients that changes in several areas of functioning are at least as important as changes in level of symptom severity when evaluating the effectiveness of the treatment. For example, employers are interested in the patient's ability to resume the functions of his or her job, while family members may be concerned with the patient's ability to resume their role as spouse or parent. Increasingly, measurement of the patient's functioning in areas other than psychological/mental status has come to be included as part of behavioral health care outcomes systems. Probably the most visible indication of this is the incorporation of the SF-36 or HSQ into various behavioral health care studies, and the fact that two major psychological test publishers offer HSQ products in their catalogs of clinical products. One will likely see other public domain and commercially available nonsymptom-oriented instruments, especially those emphasizing social and occupational role functioning, in increasing numbers over the next several years.

Other types of instrumentation will also become prominent. These will include measures of variables that support the outcomes and other therapeutic assessment initiatives undertaken by provider organizations. What one organization or provider feels is important, or what it is told is important for reimbursement or other purposes, will dictate what is measured. Instrumentation will also include measures that will be useful for the prediction of outcomes for individuals seeking psychotherapeutic services from those organizations.

4.18.9.3 Trends in Data Use and Storage

There are two areas of application in which the valuable data obtained from therapeutic psychological assessment have heretofore been overlooked or underutilized. Indications are that this will change for both in the future. One area for which assessment data has potential application is that of clinical decision-making. This of course pertains only to the use of outcomes assessment data. Generally, data gathered solely for the purpose of outcomes assessment is used for just that: the assessment of the results of treatment. This is particularly the case in large, formal outcomes management programs. As has been discussed earlier in this chapter, data gathered at the beginning of treatment can be used immediately for treatment planning purposes while also serving as baseline data that can be compared to discharge data later on.

The other potential area of data application is in the development of local, regional, and national databases of therapeutic assessment data. Patient data gathered by various providers, organizations or programs within organizations, at one or more points during the therapeutic episode, can be pooled and used for various purposes. These databases can then serve as the bases for two highly beneficial (and probably profitable) endeavors. The first is the generation of sets of normative data for various populations delineated along any number of parameters. Norms for any number of instruments or health care variables could be generated "on demand" and continuously updated to reflect trends in behavioral health care. This author is aware of one large, national behavioral health care system where such a database already exists. He also is aware of efforts at establishing cross-organizational databases of this kind.

The second benefit afforded by the information contained in these databases is that of predictive modeling. For example, the behavioral health care organization mentioned above has taken advantage of the organizational data available to it to investigate the relationships between a number of treatment, demographic and other variables and the outcomes of treatment. Subjecting the large data sets available to it to sophisticated statistical analyses has allowed this organization to determine those types of patients requiring special care or attention in order to achieve desired outcomes at the time of treatment termination. Predictive modeling can also be used for identifying variables related to other aspects of patient care, such as patient satisfaction with the care received. The possibilities for the use of data in this manner are enormous.

4.18.9.4 Trends in the Application of Technology

Clinical psychologists have not been shy when it has come to taking advantage of the technological advances that have been achieved since the late 1970s. This is no more evident than in the extent to which the personal computer and the vast array of psychological assessment software have been incorporated into their delivery of clinical services. Automated administration, scoring, and interpretation and reporting of the results of nearly all major objective tests are currently available to the clinician through PC-based software. In addition, the availability of affordable desktop optical scanners allows the clinician to maintain the portability of the assessment instruments while retaining the scoring and interpreting power of the computer for processing the test data.

To speculate on how technology will be advanced in the service of therapeutic psychological assessment in the future is a risky businesss. As has been witnessed since the late 1970s, much can happen quickly. There are, however, three areas of technologic or technology-dependent advances on the horizon to which clinical psychologists should have access in the not too distant future. The first is the availability of online administration, scoring, and interpretation and reporting of tests via the Internet. In fact, an Internet version of the SA-45 is being beta tested at the time of writing (1997). To this author's knowledge, this represents the first use of the Internet for psychological assessment purposes. It is anticipated that the Internet version of the SA-45 will be commercially available in the very near future, and it will be quickly followed by the availability of Internet versions of other assessment instruments.

The second advance is actually a technology that has been around for a while but has undergone improvements, that is, the fax-back technology that is being used for scoring and reporting of objective, paper-and-pencil tests. Essentially, the fax machine replaces the optical scanner as a means of data entry. The electronic data is entered directly into the test publisher's computer for processing and report generation. However, instead of generating a hard-copy report of results at the processing site, the report is transmitted in electronic form and sent back to the clinician's fax machine within minutes of processing. At that point, the report is printed out just like any other fax transmission. Currently, this technology is being used on a somewhat limited basis. This is partially owing to the degree to which test publishers are making this form of automated scoring and reporting available to their customers. However, in the relatively near future, one should see more tests being offered to clinicians in this manner, particularly as the technology continues to improve.

The third area of technologic advancement has more to do with the application of technology than the development of new technology. L. E. Beutler and O. B. Williams (personal communication, January 15, 1996) have taken Beutler and Clarkin's (1990) Systematic Treatment Selection (STS) model of prescriptive treatment assignment and have developed specifications for software for automating the matching of treatments, therapists, and patients. The capability of subsequently tracking patients during the course of treatment is also included in these specifications. Originally entitled *STS for Windows*, this software is now under development through a behavioral health care publishing and consulting company. Driving the STS system is patient assessment data related to six variables: subjective distress, functional severity, problem complexity, potential for therapeutic resistance, coping style, and social support. Each of these variables may be assessed through either commercially available self-report instruments or clinician rating scales developed specifically for use with STS.

When fully developed, the STS should serve as the standard for in-office treatment–patient–therapist matching and patient-tracking software. According to the developers (L. E. Beutler & O. B. Williams, personal communication, January 15, 1996), the software will include numerous features, the most important of which will be: a comprehensive treatment planning report with up-to-date references to relevant research articles and treatment manuals; automatic entry of each patient's data into a growing database that is used for treatment planning and prediction; the ability to predict the amount of symptom reduction from a specific course of therapy; a report profiling the patient's symptom status over time; a report indicating individual clinician's ability to treat specific types of symptomatology; and the ability to incorporate case notes into the patient's electronic file. The major benefits of the system include the ability to: use different assessment means (self-report or clinician rating) to obtain the information needed to drive the system; develop treatment recommendations based on information that is optimal for the patient; easily monitor patient progress on a glide path developed from the treatment of similar patients and adjust the therapy plan (if necessary) on a timely basis; and determine a clinician's therapeutic strengths and weaknesses, thus permitting the most effective patient–therapist match.

All in all, when fully developed, the STS software will combine the knowledge and expertise of a leader in the field of psychotherapeutic research with state-of-the-art technology, thus yielding a powerful decision-making behavioral health care tool. One can be assured that similar products are likely to follow once the benefits of the STS software become widely known.

4.18.10 SUMMARY

The health care revolution has brought mixed blessings to those in the behavioral health care professions. It has resulted in limitations for reimbursement for services rendered and has forced many to change the way they practice their profession. At the same time, it has led to revelations about the cost savings benefits that can accrue from the treatment of mental health and substance use disorders. This has been the bright spot in an otherwise bleak picture for some behavioral health care professionals. For clinical psychologists, the picture appears to be somewhat different. They now have additional opportunities to contribute to the positive aspects of the revolution and to gain from the "new order" it has imposed. By virtue of their training in psychological assessment and through the application of appropriate instrumentation, they are uniquely qualified to support or otherwise facilitate multiple aspects of the therapeutic process. It is the clinical psychologist's contributions to aspects of "therapeutic psychological assessment" that this chapter has sought to identify and address in some detail.

Earlier, this author identified some of the types of psychological assessment instruments that are commonly used in the service of therapeutic endeavors. These included both brief and lengthy (multidimensional) symptom measures, as well as measures of general health status, quality of life, and patient satisfaction with the services received. Also identified were different sets of general criteria that can be applied when selecting instruments for use in therapeutic settings. The main intent of this chapter, however, was to present a detailed discussion of the various therapeutic uses of psychological assessment.

Generally, psychological assessment can assist the clinician in three important clinical activities: clinical decision-making, treatment itself (when used as a specific therapeutic technique), and treatment outcomes assessment. Regarding the first of these activities, three important clinical decision-making functions can be facilitated by psychological assessment: screening, treatment planning, and treatment monitoring. The first of these can be served by the use of "down and dirty" instruments to identify, within a high degree of certainty, the likelihood of the presence (or absence) of a particular condition or characteristic. Here, the diagnostic efficiency of the instrument used (as indicated by the PPP and NPP) is of great importance. Through their ability to identify and clarify problems as well as other important treatment-relevant patient characteristics, psychological assessment instruments can also be of great assistance in planning treatment. In addition, treatment monitoring, or the regular determination of the patient's progress throughout the course of treatment, can be served well by the application of psychological assessment instruments.

Secondly, assessment may be used as part of a therapeutic technique. In what Finn terms "therapeutic assessment," situations in which patients are evaluated via psychological testing are used as opportunities for the process itself to serve as a form of therapeutic intervention. This is accomplished through involving the patient as an active participant in the assessment process, not just as the object of the assessment.

Thirdly, psychological assessment can be employed as the primary mechanism by which the outcomes or results of treatment can be measured. However, the use of assessment for this purpose is not a cut-and-dried matter. As discussed, there are issues, pertaining to what to measure, how to measure, and when to measure, that require considerable thought prior to undertaking any standard (or even nonstandard) plan to assess outcomes. Guidelines for resolving these issues are presented, as is information pertaining to how to determine whether the measured outcomes of treatment are indeed "significant."

In the final section of the chapter, this author shares some thoughts about where psychological assessment is probably heading in the future. No radical revelations are presented since no signs really point in that direction. What is foreseen is the appearance of more quality assessment instruments that will remain in the public domain, and greater application of communications technology, fax and the Internet, in particular, as assessment delivery, scoring and reporting mechanisms. Also predicted is the application of tomorrow's computer technology to available assessment data for optimized treatment–patient–therapist matching. The innovative proposals of Beutler and Williams in this regard seem to represent the state-of-the-art thinking at this time.

There is no doubt that the practice of psychological assessment has been dealt a blow within recent years. However, as this chapter hopefully has shown, clinical psychologists have the skills to take this powerful tool, apply it in ways that will benefit those suffering from mental health and substance abuse problems, and demonstrate its benefits and their skills to patients and payers. Whether they will be successful in this demonstration will be determined in the near future. In the meantime, advances will continue to be made that will facilitate their work and improve its quality.

4.19.1 INTRODUCTION

Psychologists interface with the courts in various contexts and situations. A developmental psychologist may describe a 3 year old's recognition of risk in a product liability case in which a child was injured playing with a toy. A clinical psychologist may testify about the more suitable parent in a custody dispute in family court, or may opine about a defendant's mental state when he committed murder in a criminal case. A neuropsychologist may give evidence about cognitive or brain functions in a personal injury case. Other areas of testimony might include such diverse topics as the trustworthiness of eye witnesses reports, the appropriateness of a statistical analysis purportedly linking a toxin with a disorder, test bias in screening job applicants, and the characteristics of individuals who delay a considerable period of time before reporting traumatic events.

Such qualitative variation in courtroom activities precludes coverage of all these topics in one chapter and necessitates an alternative strategy. Much of the material to follow will have a generic quality, that is, many of the points that will be raised relate to a broad array of courtroom work. However, such generic discussion will be anchored by, or mainly directed towards, the civil arena, with an emphasis on distress claims (e.g., post-traumatic stress disorder) and brain injury claims. These topics provide suitable illustration of many of the more general points that will be raised. Additionally, distress and brain injury claims are very active areas in psychology and law, and hence of likely interest to a broad audience. Although assessment is the organizing theme of the chapter, this activity is not entirely separable from the context of courtroom opinions and other collateral issues (e.g., depositions), and thus the material that follows will not be rigidly limited to evaluative methodology. Finally, readers who are mainly interested in a highly specialized area (e.g., child custody, or multiple personality in criminal cases) may supplement the material presented here with additional sources.

The chapter will begin with coverage of basic issues that frame psychologists' courtroom involvement and that are often the focus of legal proceedings, such as the core elements of civil cases and whether psychologists participate as treating professionals or as retained experts. I will then discuss, in turn, the admissibility of psychological evidence; methods for conducting and improving courtroom evaluations; and case strategies and tactics, including lawyers' main areas of attack, depositions, direct testimony, and cross-examination.

The emphasis of this chapter is far more practical than philosophical or theoretical: the main intent is to provide materials that will enhance the quality of mental health professionals' legal work. Other psychologists may take a different view than my own on the level or type of scientific backing that is appropriate for legal work, although my views on this matter are considerably more moderate than some readers might suppose (e.g., I simply maintain that psychological testimony should normally rest on fundamentally sound scientific foundations [see Faust,1993]). Further, I believe that psychology is making substantial strides, and that there are an increasing number of areas in which testimony is likely to be of considerable scientific and practical merit in the courtroom (see the upcoming revision of Faust, Ziskin, & Hiers, 1991; Faust, Zisken, Hiers, & Miller, in press). Whatever differences there might be in viewpoint about the needed level of scientific backing for legal testimony, which, of course, is ultimately a matter for the courts to decide, presumably all psychologists would agree that there is merit in increasing the quality of courtroom work: it is with that spirit and intent that this chapter is written.

Some psychologists are hardened veterans of courtroom work and others are just beginning to consider courtroom involvement. This chapter is directed mainly towards those at an intermediate or beginning level. Further, some of the points I raise are based on my experience with legal work, particularly as a consultant. I am not assuming that my experience with legal cases is necessarily representative of such cases overall, and I am not using my observations to try to reach scientific conclusions or generalizations, but rather to provide what I hope will be practical guidance.

The guidelines and suggestions for the practice of forensic psychological assessment detailed in this chapter emerge from, and are directed towards, the USA court system, and their generalization and application to other court systems vary. Nevertheless, many of the main points likely will apply to forensic work in other countries, in particular the emphasis on methods and strategies that increase the likelihood of accurate conclusions.

4.19.2 SOME KEY ISSUES AND CONSIDERATIONS IN PERSONAL INJURY CASE

4.19.2.1 Four Central Issues

Personal injury cases, which involve civil (and not criminal) law, address situations in which it is claimed that one or more individuals have not carried out some duty owed to one or more other individuals, or have not exercised reasonable care. For example, Smith may have been negligent in failing to shovel the driveway, and Jones may have slipped on the ice and suffered a broken arm. Many personal injury cases involve lay individuals, not professionals. Thus, the legal issues frequently relate to responsibilities of the general citizenry, such as exercising reasonable care when driving a car or shooting a gun.

Individuals are held to obligations and standards commensurate with the role in which they are functioning and the assumed levels of knowledge and responsibility that are expected or required. For example, in a medical malpractice case, a neurosurgeon will almost surely be held to a much higher standard in recognizing a brain tumor than a clinical psychologist with a general practice. At the same time, both the neurosurgeon's and the psychologist's responsibilities are dictated by their roles as professionals. Once they take on a patient's case, they are not only obligated to the duties that bind the ordinary citizen, but in addition the responsibilities involved in the professional care of a patient. In contrast, and obviously, ordinary citizens are not obligated to properly diagnose and treat individuals for medical or psychological disorders. The citizen may be responsible for the broken arm resulting from the fall on his unshoveled driveway, but not for interpreting the x ray or setting the cast properly.

In most legal cases, in order for a plaintiff to prevail, or at least to make a monetary recovery, four elements, and all four elements, must be proven (this also applies to malpractice cases). First, there must be a duty owed. For example, we might owe a duty to maintain our premises free of foreseeable hazards, but not to maintain our neighbor's premises. Second, it must be proven that there was a breach of duty, or that reasonable care was not exercised. For example, if we do not shovel our sidewalk, we may well have breached our duty. But if an earthquake caused our sidewalk to crack and someone fell and hurt himself before the rumbling stopped and action could be taken, the plaintiff likely will not prevail.

Third, the breach of duty must be a cause of the harm. If the person fell, but it was because her feet got tangled in the dog's leash and had nothing to do with the tools left scattered on the stoop of the shop, the business owner is not liable. Depending on the circumstances, issues, and other possible factors, the potential agents in question may need to be the main cause of the harm, a substantial contributor, or may only have to have made any type of meaningful (versus trivial) contribution. Damages are sometimes awarded in relation to the relative contribution of the cause at issue. Thus, if the event is assumed to account for 10% of the outcome, one multiplies the award by .10. In other cases, if a factor made any significant contribution, the defendant is responsible for the total damage that ensued. For example, if the defendant's careless driving caused the accident, then it makes no difference that most of the plaintiff's injuries would have been avoided had she worn a seat belt.

The fourth and final issue is damages. Assuming the first three criteria are met and the defendant is hence found to be blameworthy (i.e., liable), plaintiffs are to be compensated for any damages stemming from the event. A duty that was owed may have been breached and caused an undesired event, but if that event resulted in no damages or minimal damages, there will be little or no award (and the case, in fact, will probably go nowhere in the courts). For example, a therapist may have engaged in an egregious action, such as throwing a suicidal patient out of treatment the moment he discovered the patient's insurance had run out. However, if no harm resulted, for example, the patient did not make a suicide attempt and through some odd quirk ended up benefiting from the termination, there are no damages for which the patient is to be compensated, although the courts or a professional board could still sanction the professional.

4.19.2.2 The Four Elements and the Forensic Examiner's Task

Depending on the type of civil case in which a psychologist is involved as an expert and the particulars, any or all of the four elements discussed may be pertinent to the professional's task. In malpractice cases, for example, the professional may address each of the elements. There may be debate about whether: (a) a brief or even casual contact with a troubled person created a professional duty or relationship, or about the nature of that duty; (b) whether the psychologist has followed reasonable care in assessing suicidal ideation or has met a certain standard of care; (c) whether failure to meet some practice standard caused the harm the person suffered; and (d) about the type and extent of harm that occurred. However, in many other cases, mental health professionals do not touch on at least the first two issues, that is, whether or what duty was owed and whether it was breached. For example, a clinical psychologist usually does not testify about proper driving practices.

The issue of causation may or may not be central to the psychologist's courtroom testimony. In some cases, another expert will testify about cause. For example, a neurologist may indicate that the plaintiff's cognitive disturbance is due to brain damage suffered in the accident at issue. In such a case, a neuropsychologist might primarily address the issue of damages, or the cognitive and behavioral impairments that are present. There may be little need for the neuropsychologist to link the damages to brain injury because another professional, the neurologist in this case, has already made the causal connection. The plaintiff's attorney may prefer to leave the issue of cause in the neurologist's hands, or the neuropsychologist may be restricted from providing causal testimony. In some cases there may be multiple causal elements to be considered, one or more of which the psychologist will address. For example, the issue of whether reckless driving caused the accident can be separate from an issue such as whether the accident caused brain damage. The first question about cause involves the assignment of blame for the event, and the second the link between the event and its possible consequences. The jury could decide that an improper left-hand turn caused the accident, and that the accident caused a chronic neck condition but not a brain injury.

In other cases, however, if the mental health professional does not testify to cause, there may be no other expert who can. For example, in a malpractice case, it will likely be up to the psychiatrist or psychologist to connect a therapist's breach of duty with the plaintiff's problems, or at least those problems linked to the event (such as depression, increased anxiety, or decreased responsiveness to therapeutic intervention). If there are plausible alternative causes for the problems (e.g., substance abuse or other emotional traumas), and if the professional herself cannot determine whether there is a causal link, how can one expect the jury to make a judgment about a matter the expert cannot decide? A decent cross-examiner can thus quickly show that with all the professional's presumed expertise, she cannot say there is a link between the event and adverse functioning. This may be devastating to the plaintiff's case. In some instances, if the expert's inability to address cause comes to light prior to trial (e.g., during a deposition that is taken as part of the discovery process), this may lead the judge to place tight restrictions on the psychologist's trial testimony, or even to exclude the expert or dismiss the entire case. For example, in a toxin case in which brain damage is being claimed, if the attorney can produce no expert to help with this core element—causality—it may not be possible to prove it legally and the case may be over.

The need to establish cause also illustrates some of the differences that can arise across clinical and courtroom situations. In clinical practice, a determination of cause or etiology may make little difference because it may not alter treatment. In the courtroom, the specific cause, whatever the treatment implications, may make all of the difference. A psychologist may fail to recognize how an issue that can be of such minimal relevance in a clinical situation, and, therefore, sometimes bypassed or set aside during the course of an evaluation, might have huge repercussions at deposition or trial. This is also why, in the legal arena, it is often not enough to identify a condition as present. It may be true that Smith has brain damage, but if it was not the car accident but a toxic exposure in a different place and circumstance that caused it, the driver of the other vehicle is not responsible. It follows that careful consideration of alternate causes, including procurement of relevant documents and information, is often crucial to the psychologist's legal work.

Psychologists usually should have a basic familiarity with key legal issues in a case before they undertake, or, preferably, before they decide whether to undertake, a courtroom evaluation, and should not assume that the lawyer will convey this information. The psychologist is typically better off knowing in advance whether cause is at issue and whether the lawyer does (or does not) want the psychologist to address this matter; and whether the standard applicable to the case is a substantial versus primary contributor. Such foreknowledge may allow psychologists to identify circumstances in which they are being asked to do something that is unreasonable or beyond their expertise, or may allow them to direct their efforts towards the matters at issue. I have seen many cases in which psychologists had limited or minimal acquaintance with key issues in a case and overlooked them in their assessments or reports. It is difficult to conduct an optimal or proper examination when one does not know the specific purposes to which it should be directed. For example, exhaustive cognitive testing may be of little use if there is really no issue in the case related to intellectual functioning, or occupational functioning may not be covered thoroughly although it is far and away the most important area of dispute.

Monetary awards are intended to cover past, present, and future expenses, and to compensate for losses that follow and are due to the injury. Expenses might include damaged property, needed equipment (e.g., a cervical collar), alterations of one's home setting (e.g., a wheelchair accessible ramp), and treatment. Treatment might be one of the largest, if not the largest, component of damages. For example, in a serious brain injury case, extended inpatient rehabilitation and outpatient services may cost hundreds of thousands of dollars.

Losses might include earnings, pain and suffering, and, at least theoretically separate from the latter and where allowed, "hedonic damages." Hedonic damages refer to lost opportunities to experience pleasurable or positive events (as opposed to experiencing negative events), such as the enjoyment of attending one's senior prom. Consortium claims are also common, in which the spouse claims that the injured partner is less able to fulfill marital roles (e.g., the injured person has decreased sexual interest or capacity). With lost earnings, one considers time missed from work to date and whether the person has returned, or likely will return, to gainful employment. If the individual has resumed working, decreased likelihood of promotions or ability to compete for higher paying jobs can be considered. In the case of younger persons, projections might involve the type of jobs the individual may have held in comparison to post-injury work capacities. In principle, damages should flow from the injury. An individual who previously had a poor marital relationship should not recover for the marital problems that pre-dated the event or were caused by other factors.

The above discussion should make it clear that individuals are generally not supposed to be compensated for having a condition per se, but from the consequences, problems, suffering, or dysfunction associated with the condition. For example, if two individuals both have Post-Traumatic Stress Disorder (PTSD), but one is usually able to control her symptoms, needs limited treatment, and is functioning well at work, she is likely to be compensated much less than the individual who has broad impairment and cannot hold competitive employment or maintain intimate relationships. This emphasis on the consequences of injury is one reason it is so important for an evaluator to go beyond a label and the immediate office setting and try to appraise, if scientifically viable methods are available, an individual's life functioning (see further below). Failure to do so can result in a serious over- or underestimation of damages. For example, an individual with orbital frontal brain damage may seem relatively unremarkable on cognitive testing and structured interview but may exhibit incapacitating problems in everyday behavior, whereas another person with markedly elevated scores on personality testing and many complaints may be functioning proficiently.

Although it may fall within the psychologist's purview to describe areas of positive and negative functioning and to formulate projections over time, certain technical aspects of damage appraisal, especially their conversion to monetary values, are usually better left to others (which does not necessarily or always mean that one endorses their methods). For example, life care planners may list the equipment a brain-injured individual needs and the cost of various items, or an economist may translate conclusions about occupational capacity to numbers. Psychologists should be very careful not to undertake tasks for which they are not well qualified or knowledgeable or for which underlying methodology is dubious. As will be discussed, effective cross-examiners have refined abilities to detect weak points and to start tearing at these very locations. The credibility of an otherwise exemplary evaluation may be quickly demolished when the lawyer starts asking the psychologist about the grades he received in business classes or technical questions about calculating interest rates and cost of living increases. It often only takes one or a few instances in which an expert has been shown to express opinions in areas she knows little about before the jury assumes the expert does not know much about anything.

Also, although I will not repeat the same point over and over throughout the chapter and instead will mainly emphasize practical consequences, there are compelling ethical reasons to restrain practice in relation to level of expertise and the availability of adequate scientific methodology/backing. Parties have much to gain and lose in legal proceedings, and the hope and expectation is that the expert in a branch of science will assist juries in reaching sounder decisions than they would otherwise, something that demands some reasonable level of knowledge and scientific underpinning.

A psychologist need not go to law school to become an effective forensic examiner, but should try to understand potential differences in the clinical and legal arenas, including the basic rules or principles of procedure and just what the issues are that define the scope of the expert's involvement and task. For example, in the clinical arena: (a) we are concerned first and foremost with the client's best interests (within the bounds of ethics) and we hope the client perceives us (or comes to perceive us) as such; (b) we usually assume that clients are not motivated to deceive us for purposes of self-gain, potentially at cost to innocent parties, and we usually do not obtain collateral records specifically for the purpose of checking on their veracity; (c) we may not be particularly concerned about cause, especially if we have narrowed possibilities down to the point that the alternatives do not change treatment; and, as follows, (d) we tailor our assessment to clinical needs and treatment questions.

In contrast, in the legal arena: (a) we presumably try to render an objective opinion, even if it might conflict with the examinee's self-interests, and we (should) assume that the examinee realizes we are a potential adversary (and ought to inform him of such); (b) we recognize that examinees might be motivated to deceive us and that we need to take active steps to check on their credence; (c) we often must focus on cause and may attempt relatively fine or subtle distinctions that may not impact on treatment at all; and, as follows, (d) we need to address, where appropriate and possible, key legal questions, such as everyday functional capacities, as opposed to what might otherwise be our main concerns (e.g., subjective beliefs and perceptions).

As is also evident, in a clinical context we do not typically expect our ideas or conclusions to be subjected to cross-examination designed to counter our view or to damage our believability or character; we might feel free to engage in hypothesizing and conjecture when trying to achieve greater understanding of our patient; and we do not expect the examinee to suffer potentially devastating consequences even if his claim is worthy but we cannot defend our opinions in court. Legal evaluators try to keep in mind the eventual uses of, and challenges to, their work. They apply this awareness to guide their efforts from the start, one hopes in the direction of performing high quality work that addresses the legally relevant issues and respects the bounds of scientifically sound method and opinion.

Finally, with all this said, juries' decisions may overlook technicalities that, in theory, should be decisive or at least highly influential. For example, although in principle the plaintiff usually must prove his case (the standard often being "more likely than not" or "by a preponderance of the evidence"), other considerations may prevail. For example, in one case, jurors interviewed after the trial agreed that they thought the plaintiff probably was not brain damaged, but that in case he might be they wanted to give him enough money to pursue the treatment he might require. In other situations, one or the other side may be perceived in such a negative light that judgments that should not be swayed by such reactions may nevertheless be altered. For example, the jury may be overly generous in deciding fault in favor of the defendant because they found her honest and likeable and thought that the plaintiff was an undeserving, devious individual. An expert who fares poorly or who is perceived as dishonest can in fact do considerable damage to her own side on issues that might seem only remotely related because she may cast doubt on others, such as the lawyer who retained her.

4.19.2.3 Treating Professionals Called into Court

4.19.2.3.1 Maintaining the treatment alliance as primary

My comments distinguishing the clinical and legal contexts assume, in the latter instance, that the psychologist has been asked to perform a legal assessment and knows from the start that this is the task. Treating psychologists may be called into court and, having served until then in a clinical role, often cannot be expected to have approached the case in a manner, or to have taken the steps, expected of a legal examiner. Further, the psychologist might find certain expectations for legal examinations (e.g., taking little or nothing the patient says for granted and performing careful checks on credibility) contrary to the role of treater. Psychologists who testify in such circumstances usually are best served by openly acknowledging any limits in their methods. Any decrement in credibility associated with such limits may be more than offset by the believability often accorded to treating professionals as opposed to experts hired by one or the other side, and by the jury's relative intolerance for a lawyer who is overly aggressive with a treater, especially one who is likeable and candidly discusses shortcomings. For example, if the lawyer criticizes the psychologist for failing to obtain extensive background information, the psychologist might comment that were he conducting a legal assessment he would have sought this information, and that it might have been useful, but when the patient presented to him with suicidal ideation he was not worried about how he would look in court but about preventing a tragedy. In contrast, if the psychologist becomes defensive and insists the lack of background information is irrelevant or that such records could not possibly change his opinion, his credibility is likely to be damaged and he might no longer be perceived as the type of doctor the jurors themselves would seek out for treatment.

Treating psychologists may want to try to avoid testifying altogether, at least in cases in which they are concerned about damaging the therapeutic relationship. The specter of court can also compromise treatment relationships from the beginning. For example, parents who are considering divorce may be more concerned with impressing the psychologist favorably, just in case a custody suit eventuates and they need a helpful opinion, than about solving their problems.

When initiating assessment or beginning therapy with possible courtroom involvement looming in the future, and especially when circumstances are such that it threatens to impede progress, it can be helpful to take an immediate position that elevates the therapeutic role as primary and minimizes, to the extent possible, the likelihood that the present clinician will impact on any subsequent legal proceedings. A psychologist cannot assure a patient she will not be called on to testify in court and should think twice before assuring the patient that, even if called, she will not comply (because this could lead to serious sanctions, such as jail time). However, the therapist can say, with all sincerity, that she considers the treatment role to be primary. She can indicate that if asked to serve as a potential witness, she will tell the attorney (or either attorney) that she has not attempted to form an objective or detached opinion and is likely to be biased or strongly influenced by the role as treater, that is, that she does not have, nor has she tried to develop, the type of impartiality desired of a testifying expert. She would therefore advise the attorney to retain an independent expert to perform an evaluation and address the issues relevant to the courtroom. Some potential clients, who, in fact, are primarily interested in using the clinician for courtroom leverage may abandon treatment immediately.

If the treating psychologist conveys such a therapeutically-oriented position to the attorney, he may well retain a separate expert. Attorneys have strong reservations, if not terror, about calling witnesses that are supposedly there to support their position but that they cannot control or predict. The damage caused by an adverse opinion is usually much greater if it comes from the attorney's own witness as opposed to that of the other side. The attorney may still call the therapist, not to state expert opinions, but simply to describe facts about such things as entries in the chart or treatment costs to date. Of course, it is difficult for the treating psychologist to arrive at a satisfactory solution sometimes, because a patient, although initially endorsing the psychologist's position of neutrality, ends up feeling disappointed or betrayed when the moment of truth arrives and abstraction becomes reality. Clients also need to realize that the therapist's commitment to treatment over legal involvement is not *carte blanche*, because certain behaviors or actions (e.g., child abuse) would not only likely alter obligations but are also associated with reporting requirements.

4.19.2.3.2 Release of assessment or treatment records

Although a series of generalizations can be provided about the release of records, only limited specifics are possible given both restrictions in the author's knowledge and the complexities and idiosyncrasies that often arise. For example, situations may occur regarding minors in state custody and who has the authority to release records; special questions may be raised when the mental competence of the patient is at issue, therapists may feel a strong obligation to review records in detail with former or present patients before releasing them; psychologists may be concerned about guarding the security of test materials, the clinician may be unsure what constitutes his file (e.g., does this also include records from other providers), or records may make references to others that are not party to a suit. Malpractice cases raise an additional set of concerns; for additional details and guidelines, the reader is referred to Bennett, Bryant, VandenBos, and Greenwood's helpful book (1990).

Some psychologists believe they can assert a right of confidentiality when their records are subpoenaed in legal cases, especially if they or their patients never anticipated courtroom involvement, the legal issues seem indirectly or minimally related to the therapeutic work, and the file contains personally sensitive materials. On the contrary, confidentiality is a right of the patient, not the therapist. If the individual wants his records released (and especially if he is aware of the contents), and if there is no reason to believe the person's decision-making powers are seriously impaired, the therapist is obligated to comply. (Issues related to collateral records that the therapist has not generated or copyrighted materials, such as test items, can become complex and will not be taken up here.) Further, in civil cases in which an individual has placed his mental status at issue, the confidentiality of past or current therapeutic materials is likely to be waived, no matter what the client prefers (unless she drops her case or at least certain damage claims). There are exceptions, however. For example, some states have exceptions for alcohol or drug treatment, and juvenile records are often protected. Further, records may contain very sensitive materials that seem irrelevant to the case at hand but that could be terribly embarrassing to the client or might damage her public image and occupational endeavors. In such situations, the responsibility usually resides with the plaintiff's attorney to protest the release, or use, of the materials, although the keeper of the records (i.e., the therapist) may need to alert the appropriate party to the presence of sensitive materials in the file. A judge might choose to review the records privately (in camera), and then decide whether to release all, none, or parts of the material. As a general guide, the psychologist should not release records unless he has the consent of the patient or a court order (not just a subpoena) demanding their release, although one should not simply ignore a subpoena (see further below).

It is mistaken to assure a patient when beginning an assessment or therapy that she has an absolute right to confidentiality or that there are only a few circumstances in which records can be obtained by third parties. There are, in fact, many exceptions to confidentiality in most states, often over a dozen, and patients may end up disclosing materials that damage their courtroom cases or reputations that they otherwise would have withheld had they been properly informed. For example, an individual in a custody case may not want to tell the therapist about occasional wild sexual fantasies that he can easily resist and would never pursue.

A few additional points can be noted. First, the psychologist should not just ignore a subpoena, and certainly not a court order. This does not mean that records must be released immediately, but if the psychologist is going to resist doing so or needs more information before acting, he needs to communicate the basis for the initial noncompliance to the relevant party in a timely and proper manner. In such cases it might be wise to consult an attorney. Second, it is usually wise to assume that treatment notes can be obtained in a legal case, or at least to recognize the real possibility that some other party might gain possession of the psychologist's records. Third, do not alter records. In a malpractice case, for example, it is not only obviously unethical and illegal to alter records, but it is often fatal to the case. Some psychologists seem naive about the mechanisms, and sometimes relative ease, with which altered records can be detected. Altered records demolish the clinician's credibility, and once this occurs the case is often, in effect, over. Fourth, if in doubt, contact an attorney, or at least another professional who is knowledgeable about legal matters. Issues relating to the release of records can quickly become complex, the adversarial nature of courtroom proceedings may be foreign to the professional, and the potential consequences of improper decisions can be serious, thereby calling for caution.

4.19.3 ADMISSIBILITY

The issue of admissibility, or what is allowed into evidence, has occupied many legal scholars and has many facets that often become extremely intricate. The issues that will involve us here is when, or whether, psychologists are allowed to testify as experts, and the extent to which their testimony might be constrained. To clarify the latter point, although a psychologist may be allowed to testify, the scope of testimony might be restricted. For example, in a criminal case, she might be allowed to address issues related to symptoms of PTSD that she believes the claimed victim of an assault manifests. However, she might not be allowed to address whether the examinee's presentation fits expectations for victims of violent rape, as such testimony might be seen as unreliable and as invading the province of the jury to decide matters of fact or ultimate issues. Various types of experts with various types of credentials testify in court. Psychological testimony is usually considered to fall within a branch of science, and thus the applicable standards are those relating to the admission of scientific evidence.

Standards for admissibility often vary across federal and state courts, and from state to state, and judges may vary considerably in the way standards are applied. What one court and one judge lets in, another might bar. There is little doubt, however, that the Supreme Court's recent ruling in Daubert v. Merrell Dow (1993), which involved the admissibility of scientific evidence, is having considerable impact. Many states are guided, in large or substantial part, by these new Federal guidelines. Briefly, prior to Daubert, admissibility of scientific evidence in Federal court was decided by two sets of standards: Frye (1923), which emphasized such considerations as acceptance within the scientific community, and a separate set of Federal standards. In Daubert, the court rejected Frye, elevated the Federal standards, and further elaborated upon them. Although the exact impact and interpretation of the Court's ruling will be clarified gradually as more and more cases are decided, at least two relatively clear trends have emerged.

First, Daubert explicitly acknowledges the judge's role as gatekeeper in deciding whether or not to admit scientific evidence. This means, in essence, that judges will likely feel freer to exclude expert evidence on scientific (or purportedly scientific) matters with less concern about reversal.

Second, in a number of cases, Daubert has lead to the exclusion of evidence that might otherwise have been admitted under Frye, particularly in instances in which scientific foundations are weak (see Bersoff, 1997). In deciding whether to admit evidence and in evaluating scientific status, Daubert directs the judge to consider such matters as demonstrations (or lack thereof) of scientific validity, whether findings have been published in peer-reviewed journals, and whether the method has a known error rate. None of these considerations are necessarily dispositive, and the court did not attempt to create an exhaustive list of criteria nor to place them in hierarchical order. Thus, Daubert is very clear in situations in which all scientific indicators are either positive or negative, and increasingly incomplete in its guidance when indicators conflict (although the same basic point could be made for methods and approaches that practicing scientists and philosophers of science use to try to settle scientific disputes—see Faust & Meehl, 1992). As would be expected in such a circumstance, there has been, and undoubtedly will continue to be, considerable variation in the application and interpretation of criteria for deciding whether evidence meets the Daubert test. However, the weaker the scientific support, especially in extreme cases, the greater the likelihood post-Daubert that evidence or testimony will be excluded. Consequently, in cases in which an expert, when challenged, cannot cite any decent scientific support for his opinion or assessment methods (e.g., there are no published studies), there is a very real chance that the psychologist will be prohibited from testifying. Overall, Daubert has reinvigorated challenges to the admission of scientific testimony, the potential testimony of mental health professionals and others is being placed under much greater scrutiny, there are an increasing number of decisions in which testimony has been excluded, and some reduction of junk science in the courtroom seems to be occurring.

What does all of this mean for the mental health professional? In an increasing number of situations, especially when the scientific foundation for testimony is weak, experts can expect challenges to the admission of evidence. In Federal court and in an increasing number of state courts, there is now more than a remote chance that testimony may be limited or excluded if there is minimal scientific support for the expert's opinions or methods, or if the literature is predominantly negative. Testimony might be allowed in areas in which scientific backing is stronger, but if foundations are weak across the board the psychologist may be barred from testifying entirely. Most commonly, an objection to the admission of testimony takes place before the trial. Written documents are submitted and, depending on the judge's discretion, there may be a pre-trial hearing at which arguments are heard and experts might testify.

In some areas there seems to be little question that psychological method or knowledge meets the Daubert standard. For example, many statistical methods have sound scientific foundations. There is also a good deal known about the potential impact of mild to severe brain injuries, at least in general (as opposed to the difficulties that might be involved in assessing specific impact in individual cases). In other areas, however, psychologists may be very susceptible to Daubert challenges. For example, many neuropsychologists construct their own idiosyncratic batteries, and there may be no peer-reviewed studies on the effectiveness of these batteries as a whole. Predictions of long-term outcomes may also lack scientific foundations, or studies of their accuracy may have produced consistently negative results.

Although a psychologist might view Daubert as an unenlightened or unjustified restriction, the hurdle that it creates—that evidence purported to be scientific should have a reasonable scientific basis—hardly seems outlandish. In fact, standards of this type would seem to be something that organized psychology, with its stated commitment to science, could support. Such standards might ultimately improve psychology's position with the courts, given the methodological sophistication of many members of the field and the potential to build or extend strong scientific foundations in key areas of legal interest. For now, a psychologist might want to think carefully before agreeing to perform an assessment or provide testimony in areas with weak scientific underpinnings. Of course, this same argument certainly could be made whether or not there is likely to be a Daubert challenge. I would note in this context that although psychologists might believe that experience can partly or fully compensate for scientific shortcomings, even serious ones, the extensive literature on experience and accuracy raises major questions about this conclusion. In fact, the negative results of many studies on experience and accuracy in the mental health field have been noted by diverse individuals (e.g., Faust, 1984; Garb, 1989; Brodsky, in press, the latter being a revision of his earlier views [1991]).

Even if the courts allow testimony on some topic, a psychologist may feel that the state of knowledge is insufficient to develop trustworthy opinions and thus may opt not to be involved. Just as the courts may err in excluding testimony, they may err in admitting it; and it is a dubious position for a professional in a branch of science to assert that so long as it's good enough for the courts it is good enough for me. Given psychologists' methodological knowledge, situations certainly can arise in which the professional believes that a judge has overestimated the scientific standing of a test, method, or assertion and that, instead, knowledge is very shaky or dubious. Most psychologists' courtroom involvement is voluntary, and there is usually no external authority that compels the psychologist to testify if she does not wish to do so, or that will invoke official sanctions for nonparticipation. In these situations, psychologists can apply internal or professional standards in deciding on their courtroom involvement. (For a more extensive discussion of dimensions a professional might consider when determining a method's readiness for the courtroom, see Faust, 1993).

The court does not decide admissibility solely on matters relating to science. In addition, testimony must be relevant to the issue at hand. For example, a psychologist might be a first-rate authority on test bias, but the topic might not arise in the case, or it might be so secondary or remote to any of the matters in dispute that the judge excludes the expert. Additionally, the expert must contribute something over and above what the jury knows or can determine on its own. For example, if the defendant's left foot has six toes and webbed feet and a plaster cast matches the pattern exactly, the jury probably does not need a footprint expert to provide commentary on the resemblance.

Experts also need to have adequate credentials. Usually, before opinions are expressed about issues in the case, the lawyer has the psychologist recite her credentials and then offers (proffers) the witness as an expert in some area (e.g., clinical psychology or PTSD). The expert should have credentials to support the offer. Psychologists may not realize that the standards judges apply when deciding whether to qualify the expert are often relatively minimal (e.g., a Ph.D. degree and some education and training in the area) rather than lofty, or that jurors may have difficulty separating, or care little about, differences in credentials that might strike the professional as weighty. A few publications might seem about as good as 20 to a jury, and a Ph.D. is likely to be an impressive degree whether or not it came from a big-name university. Ironically, some experts create major problems for themselves by failing to represent their credentials with a high degree of accuracy, when the difference often would matter little to a juror or to a judge evaluating qualifications. For example, an expert might exaggerate the number of patients seen with a particular problem, or might represent himself as a graduate of an APA-approved training program when, in fact, the program was accredited after the time of graduation and the listing is consequently inappropriate.

Take the last example. If the credential is listed accurately, the psychologist might be able to indicate, perhaps during his direct, that his program gained APA approval shortly after he graduated. The psychologist could further indicate that although the APA, in essence, approved the same program he attended, it would be technically incorrect for him to list himself a graduate of an APA-approved program, and he would not want to create a false impression. A juror is unlikely to give this a second thought, and it might even be a plus as it conveys honesty. In contrast, the following cross-examination illustration shows what can happen with even a seemingly small misrepresentation:

> Question (Q): Doctor, is there anything you'd like to correct in your direct testimony before I start asking you other questions?
> Answer (A): No.
> Q: Doctor, is there anything about your credentials you may have stated in error?
> A: No, not to my awareness.
> Q: Doctor, do you remember raising your right hand before you started to testify?
> A: Of course.
> Q: And during that oath, you gave your word that you would tell the whole truth, isn't that correct?
> A: Yes, I did.
> Q: And doctor, you told us, did you not, that you were a graduate of an APA-approved program. Wasn't that your testimony?
> A: Yes.
> Q: That was a misrepresentation, wasn't it?
> A: Absolutely not.
> A: And your status as a graduate of an APA-approved program, that's the same representation contained in your resume, isn't it?
> A: Yes.
> Q: And this is the resume you send to lawyers, and have presented in court many times, isn't that true?
> A: Well, I don't know about many times, but it is the information I have provided.
> Q: It is the same information you would present to patients, would you not, if they asked you whether you came from an APA-approved training program?
> A: I'm not sure a patient would ask such a question.
> Q: Doctor, I'm sorry if my question was unclear to you. If asked by a patient, you would tell them that you were a graduate of an APA-approved program, correct?
> A: Yes.
> Q: Then let me ask you one more time. You are telling the ladies and gentlemen of the jury that it is true, without qualification, that you are a graduate of an APA-approved program. You are giving us your word, is that correct, just like you promised to be honest about the other areas in which you testified?
> A: Yes.
> Q: And, doctor, you graduated in 1985, isn't that the case?
> A: Yes.

The lawyer can then produce an issue of the American Psychologist that includes the section indicating that a psychologist cannot describe his- or herself as a graduate of an APA-approved program unless the program was accredited at the time of graduation. Things can almost only go on a disastrous downhill course from there. For example:

> Q: Having read that, and seeing the listing for your program and the date of approval as 1990, the truth is you are not a graduate of an APA-approved program, isn't that the case?
> A: The listing is probably in error.
> Q: Is that right doctor? I'll tell you what, we can check on the listings from other years of the American Psychologist, which I have on

> the table here, and the sworn statement I've also obtained from the director of your graduate program. Do you think that will help clarify the truth of the matter?

A misrepresentation of this type can be fatal in not only the instant case, but in future cases. For example, in a subsequent case, a lawyer might ask the expert whether she has been busy calling all of the judges, lawyers, and patients with whom she's been involved to inform them that she misrepresented her credentials.

4.19.4 ASSESSMENT METHODS

In this section I will present various "tips" for performing legal assessments. Many of these guides apply similarly to conducting quality clinical assessments, although there are also a number of features distinct to forensic work.

4.19.4.1 Informed Consent

The fact that an evaluation is being performed for legal purposes typically does not alter the need to obtain informed consent before proceeding. The nature and purpose of the assessment should be presented, and it should be made clear that the clinician's primary obligation is not to advance the examinee's interests but to address certain questions, whether or not the conclusions help or hurt the individual's case. The expert should indicate who retained him, such as plaintiff or defense counsel, or judge. The expert should explain that his role is to perform an evaluation and not to provide treatment, and thus that there is no doctor-patient relationship. (This certainly does not mean the psychologist should not make treatment recommendations she deems appropriate or helpful.) At this point, the examinee may not consent to the procedure, which, in civil litigation, and often in criminal cases, is his perfect right.

There are cases in which experts are retained to perform evaluations, but with the understanding that they themselves may undertake treatment if they deem it appropriate. For example, the plaintiff's attorney may retain an expert she esteems to perform a neuropsychological evaluation of head trauma and, as needed, to provide rehabilitative services. The involvement in the dual role of forensic examiner and treater can create complications. For example, once engaged in a therapeutic relationship, it may be difficult, when it comes time to testify, to be as objective as one otherwise might be or to express views that will likely harm the plaintiff's case. Also, challenges can be raised about a financial incentive to diagnose disorder in order to engage the individual in treatment for which one can charge. For these and other reasons, it is probably best, when possible, to avoid serving as both a forensic examiner and treating psychologist.

4.19.4.2 Clarifying Referral Questions and Deciding Whether they are Appropriate and Within the Clinician's Expertise

Lawyers usually make initial contact with an expert on a specific case by written correspondence or phone. Such communication will commonly eventuate in a request to perform an evaluation and perhaps some commentary about the questions the lawyer wants the expert to consider. At times, such requests are vague. For example, the lawyer might ask the expert to evaluate psychological status but not even specify whether she is primarily interested in cognitive or emotional status, or both, or neither.

Vague questions may reflect the lawyer's lack of familiarity with issues in the mental health field, and the expert should attempt to clarify just what is at issue in the case, such as the possibility of brain damage, emotional disturbance in response to a traumatic event, present and future work capacity, malingering of mental disorder, or whatever. The lawyer may be unsure about what a psychologist, or the expert in question, does and does not do and can and cannot do; and the psychologist may need to gain some familiarity with the file before a more productive conversation is possible or greater clarification can be achieved. For example, the lawyer may not realize that psychologists cannot prescribe medicine, that not all clinical psychologists are trained to evaluate neuropsychological status, or that many psychologists are not fully prepared to evaluate members of minority groups. Or, they might not realize that psychologists often provide treatment services, that many clinical psychologists are very familiar with various matters involving psychotherapy, or that the condition in question has a grave prognosis and that this issue would seem highly relevant to the plaintiff's case. It is not that the psychologist should do the attorney's job, but rather that the psychologist's input may be needed to hone in on relevant issues in the case or what is and is not possible to accomplish through a psychological evaluation.

Referral questions also need to be unobtuse so that the clinician can determine whether the required scientific foundations exist to provide informed answers, and whether she has the requisite expertise. It is not only ethically questionable to take on issues or questions for which one lacks the needed knowledge, but it can easily lead to courtroom fiascoes. It is rather unnerving to have to admit on cross-examination in open court that this is only the second case of Fisbee's disease one has seen and that almost all of one's scientific knowledge on the topic was acquired through concentrated reading during the last week. This from the same expert who has contended, in effect, that the jury should defer to him over Dr. Jones, who has written the seminal work on the disorder and has acquired exhaustive knowledge about the condition through years of study. The psychologist is also likely to embarrass herself if a well-prepared and knowledgeable lawyer begins to ask about specifics. For example, someone who attempts to acquire quick knowledge about neuropsychology is unlikely to know what the abbreviations HEENT and GCS in the emergency room record mean, or may startle the jury when the response to the inquiry, "How many journal articles have you read devoted exclusively to mild head injury in the last 5 years," is, "None." There is a saying in aviation that there are old pilots, and there are bold pilots, but there are few old, bold pilots. This might be remembered as one engages in internal debate about whether or not to take a case. The psychologist might get by with questionable work for some time, but a single encounter with a skilled and well-prepared lawyer can inflict serious, long-term damage.

4.19.4.3 Access to Information

As will be seen, the quality of legal evaluations, and how well they stand up under scrutiny, often depend on the thoroughness of information gathering. Further, the time at which information is received can matter a great deal. For example, a psychologist who forms an opinion rapidly and in the face of inadequate information and who never revises his views in the slightest way, even after obtaining a great deal of additional information, may not seem credible. Also, a jury might look askance at an expert who reaches opinions and perhaps issues treatment recommendations, or even begins treatment, well before much of the information has been obtained, especially if that information was readily available. For example, many experts, who may have completed their reports a year or more earlier, indicate that they received or reviewed additional key information the morning of the deposition or the night before their courtroom appearance. It might be difficult for the jury to believe that the psychologist could be completely dispassionate in her use and weighting of the additional information under such circumstances.

Further, given the uncertainties and ambiguities that often exist in our field, it would be surprising if considerable amounts of new information did not contain at least some evidence contrary to our conclusions, or even evidence that required new areas of inquiry or raised serious questions about the initial opinion. Receiving such information at a late date can therefore create major difficulties on the stand. For example, the expert might be asked a line of questions like the following:

> Q: Don't you agree that mild head injury and the effects of serious alcohol abuse can look similar on cognitive testing? (If the expert disagrees, a statement he may have made in his deposition or in other cases confirming this assertion can be raised.)
> Q: And didn't you describe the level of drinking that can result in abnormal performance on cognitive testing?
> Q: And didn't you indicate that one of the ways you ruled out alcohol as a factor in Mr. Smith's testing results was his telling you that he had almost never touched a drop in his life?
> Q: Until yesterday, when attorney Jones gave you the records, you were unaware of Mr. Smith's previous treatment for alcohol abuse, weren't you?
> Q: So, when you formed your opinion and issued your report, you had not seen the treatment records describing Mr. Smith's history of alcohol abuse, had you?
> Q: Surely this is the type of information you would have preferred to have known about when you conducted your evaluation, isn't that correct? (The lawyer is unlikely to care much, and may even welcome it, if the psychologist wants to fight her on this point, because it will probably seem unreasonable to the jury and further compromise the expert's standing.)
> Q: And had you had this information, you would have asked additional questions about substance abuse, wouldn't you?
> Q: You would have asked questions to find out whether Mr. Smith drank to the point that you would expect abnormalities on the testing, isn't that right?
> Q: But it's too late to ask those questions now, isn't it?

An expert who denies the import of such questions may lose all credibility with the jury.

Many lawyers will not know what records a psychologist needs to perform a proper evaluation (see more on this below). Thus, it is up to the psychologist to inform the lawyer. The mechanics for obtaining information (as opposed to a decision about what information to obtain) can be worked out in different ways, although it is often appropriate for the lawyer to do the needed leg work. It can be very difficult or impossible to obtain certain types of information (e.g., earlier school records in the case of an elderly individual), but it may become obvious that a lawyer is not really motivated to carry out the psychologist's requests and rather wishes to control the flow of information. This reluctance and attitude may severely compromise the quality of the evaluation and place the psychologist in a vulnerable position. For example, on deposition, an expert might be asked about the type of information she routinely procures, or prefers to have, when performing a comparable evaluation. Procedures followed in similar cases in the past might be raised. Discrepancies between the usual and present case can be pointed out, and the expert can then be asked to explain the reasons why the current evaluation is so much less complete, the extent to which gaps in information compromise the trustworthiness of the conclusions, and who has controlled the flow of information. A careless response to the effect that such extensive information is unnecessary can lead to such questions as, "Are you telling me that when you gathered far more extensive information in your many other cases and charged thousands of dollars for the totality of your time reviewing those materials, all that was unnecessary?" An expert who is true to the oath and admits that the lawyer exercised control might be asked whether lawyers taught their assessment courses in graduate school or whether it is a routine procedure when performing a psychological evaluation to consult a lawyer in order to determine what information the professional needs.

An expert might also contemplate whether she wants to be involved with a lawyer who tries to exercise this type of control. There is a big difference between a lawyer pointing out legal technicalities that fall within his purview (e.g., what standards of evidence will be applied or what exactly is being disputed in the case), and one who tries to control how the expert performs activities that fall within the psychologist's professional domain. One way to handle possible differences in viewpoint on such matters is to tell the lawyer that one will feel compelled to express reservations about one's conclusions given the present restrictions the lawyer suggests. Both parties might then make more informed decisions about course of action, including whether to part ways.

This does not mean that every difference, even a very small one, necessitates an all-or-nothing stance, that the lawyer will never have a compelling counterargument, or that all such differences reflect a lawyer trying to control the expert. For example, a record a psychologist might ideally like to have may really be very remote to the issues in dispute and extremely difficult and expensive to obtain. Or, due to time limits imposed by the court, a psychologist may have to decide whether to perform an evaluation before all of the desired information is obtained. The psychologist might decide to go ahead, but to be sure the report contains an explicit statement describing the circumstances and indicating that opinions are subject to change or elaboration as more is learned. However, psychologists who take the long view probably should err on the side of caution. There are certainly some attorneys who wish to control access to information in order to increase the chances of a desired result, or who plainly want to manipulate the outcome. A psychologist will not only be on safer ethical ground but likely to have a much longer career as a forensic evaluator by avoiding such lawyers.

4.19.4.4 Design of Assessment Procedures: Some Do's and Don't Do's

4.19.4.4.1 Use the best available methods

It is important for psychologists to use the best available methods, not only to maximize the probability of reaching accurate conclusions, but because their work may be placed under intense scrutiny in legal proceedings. For example, the psychologist may be asked a series of pointed and specific questions about technical issues. Good attorneys can have a remarkable ability to pick up quasi-expertise rapidly, retain it, and generalize it to new contexts. An occasional attorney will ask questions about such matters as false-positive rates, standard error of measurement, or criterion-based validity with a proficiency that can shock an unprepared expert. Attorneys may also retain consultants to scrutinize records, educate them about technical matters, and provide them with background literature on the methods used in the case in order to better prepare for depositions and cross-examination.

Psychologists may use tests with poor normative information when better choices are available, or may use old or obsolete norms when more contemporary or complete normative information exists on the same test. For example, many neuropsychologists still use earlier norms for the Halstead-Reitan Battery (Reitan & Wolfson, 1993), which are decades old and which show a marked propensity to overdiagnose certain groups of individuals, such as older and less educated persons. More recent norms of the type that Heaton, Matthews, and Grant (1991) developed, which adjust for age, education, and gender, can decrease overdiagnosis considerably.

Additionally, norms developed for one group of individuals may not be wholly applicable or may create major problems when applied to other groups of individuals. For example, norms for measures of motor speed developed with young individuals may be applied to the elderly, or norms developed among members of the dominant culture in the USA may be applied to recent immigrants with very limited English proficiency. Psychologists may be unaware of specialized normative data that have been developed for differing sociodemographic groups or, when such information is unavailable, may act as if the application of norms developed with one group to another group with distinct differences could not possibly raise any particular concerns or issues. When these types of problematic practices occur, lawyers can introduce materials from such sources as the Standards for Educational and Psychological Testing (APA, 1985), which describe the need for normative data appropriate to the individual under consideration.

For a substantial number of psychological tests, there are inconsistent sets of norms that may lead to very different interpretations. For example, depending on the norms used for the Halstead-Reitan Battery, the number of errors on the Category Test that falls two standard deviations beyond the mean may be less than 50 or more than 100 (see Faust et al., 1991). In the case of the Auditory Verbal Learning Test (AVLT) (Rey, 1964), a list learning task, many psychologists rely on the original norms developed many years ago in France with relatively small samples. There have been many subsequent studies showing that those norms are too demanding for many groups (e.g., Bolla-Wilson & Bleecker, 1986; Wiens, Crossen, & McMinn, 1988). A psychologist may be asked questions like the following on this topic:

> Q: You told us that the plaintiff had problems on the Smith Memory Test, isn't that correct?
> Q: And the Smith test is the one with the list of words, like a grocery list, correct?
> Q: The standards you used to decide what was normal for the Smith Memory Test were developed more than 50 years ago, isn't that correct?
> Q: Those standards were developed in another country where they speak a language other than English, isn't that correct?
> Q: And there have been many studies published in the United States criticizing the use of those standards with today's Americans, isn't that true?
> Q: There are more than 10 recent studies that would classify Mr. Smith's very same performance as perfectly normal, isn't that true?

At times, it is clear that one set of norms has been better developed than another, or it is obvious that the findings from one study deviate markedly from those of most or all other studies. Unfortunately, at other times, the underlying basis for conflicting norms, or the most appropriate choice among competing norms, is unclear, creating something of an impasse. A psychologist might consider the merits (or lack there of) of using such tests, especially if tests with a better or clearer normative base are available that are designed to assess comparable areas.

Lawyers may also raise questions about other technical qualities of tests, such as reliability and validity. Some psychologists may see such questioning as meddlesome or something akin to badgering. However, standing on these technical qualities can be all important in assessing the likelihood of an accurate result, they are certainly fair game, and they often do need to be critically appraised. A psychologist may be surprised about the occasional lawyer's sophistication on these topics. For example, on deposition, one might be asked:

> Q: In the language of your field, test-retest reliability refers to the stability of test scores over time, isn't that true? (If the expert is evasive on this and other questions, the attorney may call her own testing expert to provide appropriate and clear answers and to show, in effect, that the opposing expert was being less than genuine.)
> Q: Isn't it a basic tenet in your field that tests that lack satisfactory reliability will also lack satisfactory validity or accuracy?
> Q: Test-test reliability is often measured by the correlation coefficient, isn't that true?
> Q: Correlation coefficients can range from .00 to plus or minus 1.00, isn't that correct?
> Q: And in general, higher correlation coefficients are better, or indicate a higher level of reliability, isn't that correct?
> Q: Isn't it true that (a prominent psychologist in the area of measurement will be named here) considers a test-retest reliability of .80 to represent a minimal standard? (If the expert does not acknowledge the author or source, there are other ways to get at the same thing, such as by asking what authorities on testing the expert respects, or about texts and

journal articles that were used in the expert's education and training.)

Q: You've not published your own text on psychological testing, have you?

At trial, after reintroducing these topics in clear and understandable language for the jury, the lawyer may proceed to show that various tests the psychologists used do not meet the standards for reliability the witness affirmed and thus, by the witness's own reckoning, cannot be trusted.

Of course, issues related to reliability are important not only because they can lead to courtroom embarrassment, but because adequate reliability is often necessary for reaching accurate conclusions. For example, deficient reliability can impede or cripple interpretive strategies that psychologists often consider essential, such as comparisons between test scores and pattern analysis. If reliability is low, the standard error of measurement of the difference $(\mathrm{SEM})_{\mathrm{diff}}$ may be so great that there are likely to be frequent false-negative and false-positive judgments about whether true contrasts exist across tests. When comparing test scores, and especially when analyzing test score patterns, error is usually additive. Stated differently, the level of measurement error will exceed, sometimes by a great margin, the average level of error per test (with the margin expanding rapidly as the number of scores considered together as part of pattern analysis grows).

Test validity is not a global quality, and hence there is little meaning to a statement like, "The Fisbee Test is highly valid." Rather, validity is a specific quality, and a test that is highly valid for one purpose and with a certain population may lack validity for other purposes and with other populations. That is, validity refers to the interpretations given to test scores and not to the test itself. Therefore, when selecting tests, it is important to go beyond general information and to become familiar with research on specifics, in particular the specifics involved in the current application.

Particularized questions about validity are often essential to legal work because many of the issues psychological tests were originally designed to answer are different, in subtle or not so subtle ways, from those commonly asked in the courtroom. For example, in a criminal case, it may be of much greater interest to determine an individual's mental state at a previous point in time rather than in the present. The possibility of malingering and the need to evaluate for it are often considerably greater in the legal context. The differences that can exist in the purposes of traditional psychological tests and the questions that arise in the courtroom have led a number of psychologists to develop instruments specifically designed to address legal issues, such as competency to stand trial (see Grisso, 1986) and malingering of psychological disorder (see Rogers, 1997a). Psychologists who conduct legal evaluations, especially in areas that traditional psychological tests are not designed to appraise and for which there is little or no research on these measures, might be well advised to become familiar with specialized methods, if they are not so already.

Along related lines, although one test may have usually outperformed another in comparative studies, important exceptions may exist in specific areas. For example, although Test A may be generally better than Test B, there may be much more extensive or positive research on the capacity of Test B to distinguish between the effects of alcohol abuse versus mild head injury. Such differences in level of background research might dictate a reversal of usual test selection. Such possibilities again suggest that specific knowledge about specific test qualities can greatly facilitate test selection.

Legal evaluations may also be weakened by the use of obsolete tests, particularly when more contemporary and improved versions are available. Some tests do not age well, and should the lawyer present some of the items in the cross-examination, jurors may be left shaking their heads and wondering, in fact, who these supposedly famous people that the test required the examinee to identify might have been.

Psychologists may substitute short, and clearly inferior, versions of full or standard forms of tests. Shortened versions commonly are far from perfect predictors of results on full versions of tests. As full versions of tests are usually rather imperfect predictors of the matters at issue, using shortened versions adds error to error (Ziskin, 1995). The lawyer might also be able to introduce statements by the test creator arguing vehemently against the use of short forms.

In some cases, alternate or parallel versions of a test are available, but one of the versions has been much more thoroughly researched than the other and there is inadequate research about the equivalence of the alternative forms. Especially if the test is administered only once, it would seem prudent to use the better known alternative. Similarly, for some tests, there are alternate administration formats, or alternate test materials or equipment, with one version being far better investigated than another. For example, a psychologist may use certain equipment when administering a test of finger tapping speed, but may depend on norms developed on other equipment when interpreting the results.

Although the use of one piece of equipment over another might seem like a trivial matter, research may show, as it does in this case, that different equipment can yield different results (e.g., Brandon, Chavez, & Bennett,1986). The psychologist may also have to admit that he ignored the stern admonition of Dr. Reitan, a co-creator of the very battery he used, to avoid alterations in original equipment lest one compromise the interpretive value of results (Reitan & Wolfson, 1993).

I have consulted on more than a few cases in which psychologists used badly deteriorated test materials or made up their own "duplicates" of tests that contained errors in instructions or in the reproduction of stimulus materials. For example, in one case, the stimulus sheets for a task requiring color discrimination were more than a little faded; and in another, a homemade form for an intelligence test contained alterations in standard test instructions. Still another case involved Part B of the Trail Making Test (Reitan & Wolfson, 1993), a paper-and-pencil task, which contains numbers and letters randomly arranged on the page that are to be connected in order (e.g., 1-A-2-B-3-C, etc.). The stimulus materials are arranged so that the continuing line to be drawn from one number or letter to another never crosses over itself, thereby keeping the spatial layout relatively clean or simple. However, the psychologist had mispositioned the stimuli such that the respondent now had to crisscross over the line repeatedly, a new variation that seemingly made the task much harder. In other cases, reproductions of materials from personality questionnaires contained errors: it must have been difficult for the examinee to answer unintended alterations of original items from the Minnesota Multiphasic Personality Inventory (Hathaway & McKinley, 1951, 1983) such as the following: "I sometimes feel that there is a tight bank around my head."

4.19.4.4.2 Obtaining adequate information

One of lawyers' most common cross-examination tactics is to bring up concrete facts that contradict, or seem to contradict, the psychologist's opinion. For example, in a case of purported PTSD, in which the psychologist has described the plaintiff's decided tendency to avoid reminders of the accident, the lawyer may ask if the psychologist knows that the plaintiff replaced the totalled vehicle with a new one of the same make and model and regularly drives on the road where the accident occurred when an alternative route is easily accessible. In general, courtroom opinions will likely be much more vulnerable to cross-examination if the psychologist lacks an adequate factual base. Reaching accurate conclusions about key matters also often demands such information. Consider again that legal evaluations often raise questions that differ from those that are most common in clinical settings and may well call for information gathering that differs in type and amount.

As discussed in Section 4.19.4.3, when information is received can be crucially important. For example, jurors are likely to react negatively if they find that the psychologist formed opinions very early and far before most information was reviewed, or waited until the eve of trial to perform a thorough analysis of records, years after issuing treatment recommendations intended to guide other professionals. The latter can look especially bad if the psychologist has insisted he places his role as a treater above that of courtroom expert and cares deeply about the examinee's welfare. The jury almost cannot help but wonder if this is impression management and disingenuous. After all, if the psychologist really is concerned about the individual, he would not have made important treatment recommendations on the basis of such incomplete information. Also, as noted, new records may call for entirely new lines of inquiry, and if materials are not examined until the 11th hour the opportunity may be lost. All of this again emphasizes the need for the psychologist to be thorough in information gathering in legal cases and, to the extent feasible, to obtain records earlier rather than later.

Information gathering usually must go beyond self-report and testing and include various types of collateral information, such as past and present medical records and reports, employment records, school records, and materials memorializing other's observations or reports about the plaintiff. It may be especially useful to access the observations of a neutral party who knew the plaintiff before and after the accident or event. These types of observations may be contained in background records (e.g., work evaluations) or in depositions, which may be as good or better than interviews. Information gathering will usually address at least four issues: a) prior functioning, b) current everyday functioning, c) possible causes or alternative explanations for the plaintiff's presentation or reported problems, and d) the accuracy and completeness of the plaintiff's report to the examiner.

To elaborate on these four areas, an analysis of prior functioning is important in order to determine the presence and possible extent of changes in functioning. In principle, plaintiffs are not to be compensated for problems that pre-date the injury. Typical psychological assessment methods, by themselves, are often limited tools for determining prior abilities or adjustment. For example, psychological testing results usually provide, at best, inferential or indirect evidence. Much more direct information about prior functioning often is available or can be made available. Thus, extensive occupational records showing excellent and steady job performance are likely to be considerably more helpful and trustworthy in developing an understanding of past work function than inferences based on an IQ test. There are also, often, similarly direct and independent sources of information about current functioning that can supplement and extend, and serve as means to check on, impressions formulated from the plaintiff's report and testing.

Using collateral records to help appraise the accuracy and completeness of the plaintiff's report is essential, not only because there is a heightened risk of misrepresentation in legal cases, but because inadvertent misrepresentations can occur and lead to over- or underestimates of adverse changes. For example, depressed individuals may understate, or individuals with serious brain injuries may overstate, their current level of functioning. Also, the plaintiff may simply have forgotten, or may be unaware of, important matters. For example, she probably will be unable to state precisely when her developmental milestones were achieved, may be uncertain about or unaware of performances on past standardized testing, or may be confused about prior medical diagnoses. A psychologist is in an especially compromised position when he does not try to obtain collateral information in areas in which the deficits he assumes the examinee manifests would seem to impede that person's capacity to provide the very information the professional seeks. For example, the expert might ask a person, who he believes has serious problems in long-term memory, about remote historical events.

Many sources of information are usually potentially available to psychologists conducting legal evaluations. Past testing frequently can be obtained through such sources as school records, and sometimes through military records and pre-employment evaluations. Past work records, medical records, pharmacy records, psychological and counseling records, and criminal records may also provide important information or leads about previous strengths and weaknesses and about possible causes for presenting problems. One can examine these materials for the facts they provide, and also for direct and indirect indicia of prior functioning and capacities. Forms completed in the past, for example, may allow the psychologist to determine whether his impression about decreased mechanical writing quality is accurate. Information about post-incident and present functioning may be available from similar and other sources, such as work records and work samples. Further, some individuals who stop working return to educational activities or develop new hobbies. Contemporaneous school records may suggest that a brain-damaged patient over-reported current academic performance. Alternatively, they may show abilities to learn new skills and to engage in problem solving that raise very serious questions about the accuracy or meaning of low scores on measures designed to tap such functions.

The plaintiff's deposition may provide an extended sample of various cognitive functions, such as language use and the ability to attend to questions. I have been involved in cases in which plaintiffs with purportedly severe attentional and language comprehension problems answered hundreds of questions without a single one having to be repeated and seemed to have no difficulty understanding the lawyer's inquires, despite the recurrent use of complex grammatical structure and relatively sophisticated vocabulary. Review of the plaintiff's deposition may also provide experts with important information that is not contained in other records, such as materials on past accidents or problems with the law.

Legal cases often involve questions relating to quality of life, day-to-day functioning, and work capacity. Psychologists may not habitually collect detailed information in areas that are directly relevant to these concerns. For example, an accident may have forced the injured individual to discontinue various enjoyable activities or hobbies. It is difficult to address impact on day-to-day functioning unless one develops a reasonably detailed description and chronology in this area. A courtroom evaluation in which the psychologist assigns a diagnosis, describes areas of maladjustment, often in abstract terms (e.g., Smith has elevated anxiety levels), and presents a general treatment plan may be of minimal help in understanding possible damages or the specific consequences of an injury. Too many legal evaluations are devoid of an adequate connection with the individual's day-to-day life and functions. It is usually much more helpful to know what the individual did before and can and cannot do now due to his reduced memory than to know the percentiles for his scores on memory testing.

In the area of work capacity, except in gross or obvious cases, it would often seem difficult to reach a well-grounded conclusion about possible return to former employment without a reasonable understanding of prior job requirements. A general label or description may not be sufficient, and one needs to understand just what the job required. In one case, the plaintiff indicated he operated a machine that made paper bags, which the psychologist assumed was a rather simple matter. However, it turned out that the equipment was incredibly complex and often required intricate adjustments involving dozens of steps. Psychologists need not feel obligated to address work capacity, even if it is an issue in the case, should it involve matters with which they do not feel sufficiently informed or if they do not believe the required scientific backing is available to perform this analysis. (It would be much better to inform the attorney of this limit in advance, however, so that counsel can consider retaining an additional expert and is not unexpectedly stuck at trial with no one to address occupational issues.) The point is that if a psychologist is going to address work capacity, certain information would seem essential.

A well-rounded picture of an individual and an understanding of her functional capacities is also likely to touch on such topics as self-help skills, household activities and chores, interpersonal relationships, activities outside of the home and job, the state of the marriage, child care responsibilities and capacities, and travel activities. The examiner may also want to know who handles other responsibilities of major importance, even if they come up only occasionally, such as large purchases. There is something potentially inconsistent about a claim of gross reductions in mental ability and the fact that this same individual, with the spouse's full blessing, handled delicate and complex negotiations for the acquisition of the new home.

In this vein, the psychologist might be especially alert to, and actively look for, circumstances in which the benefits and disadvantages of being capable and incapable are reversed. For example, it might be to the plaintiff's advantage to appear quite disabled during the psychological evaluation, but quite capable when applying for a business loan. Consistency in presentation across such circumstances, even when the individual has a great deal to lose, suggests something about the genuineness of incapacity. In one case, a plaintiff in a psychological injury case was also embroiled in a unrelated custody battle. The plaintiff had undergone independent psychological evaluations in each case. On the evaluation conducted for the personal injury case, he endorsed many items in the pathological direction on the MMPI, but reversed these answers in virtually every instance in the custody case: when it was to his advantage to claim disorder he claimed disorder, and when it was to his advantage to claim psychological health he claimed health.

4.19.4.4.3 Conduct technically proficient evaluations

It is not unusual for opposing counsel to obtain the psychologist's complete file, scrutinize it closely, and have her own expert review it as well. Technical problems with the examination may well be uncovered and cause difficulties.

Some of the more common problems I have observed in psychologists' courtroom work include errors in scoring psychological test items and in summing and transforming scores. I have reviewed cases in which psychologists made dozens of scoring errors or miscalculated standard scores by 30 or 40 points. In fact, the psychologist's errors may be close cousins to those he used to diagnose disorder in the plaintiff. The psychologist might then face a series of questions like the following:

> Q: You told us that Ms. Smith made errors on simple math problems, and that this entered into your conclusion that she is brain damaged, correct?
> Q: You made errors on simple math problems also, didn't you.
> Q: You told us that Ms. Smith sometimes did not attend to important details when performing paperwork, and that this was another piece of evidence suggesting brain damage, isn't that true?
> Q: You forgot to date a number of your test records, isn't that correct?
> Q: Dating a test record might be considered an important detail when performing paperwork, isn't that correct?
> Q: And you told us that Ms. Smith sometimes failed to follow fairly simple directions and that this was another indication of brain damage, correct?
> Q: Doctor, the instruction you had to follow, "Stop testing after five consecutive errors," is not complex, is it?
> Q: And you failed to follow this direction on multiple occasions, isn't that correct?
> Q: Let me see if I have this right doctor. When Ms. Smith makes errors, they indicate brain damage. When you make errors, they're just errors? Strike that, I withdraw the question.

In other cases, psychologists may violate standard testing procedures without any clear or compelling rationale. A psychologist in one case repeatedly terminated tests prematurely, calculated scores as if this had never occurred, failed to mention these alterations in procedure in her report, and had even published an article on the need to adhere exactly to standardized administration formats. Fortunately for her, the case settled before trial. There are certainly situations in which a test must be terminated prematurely or it is sensible to alter procedures (e.g., dividing a test that is preferably administered in one sitting into two sessions due to the onset of extreme fatigue part way through), but these departures should be recorded and described. What is hard to justify is altering standard procedures without any good reason. Psychology can be difficult enough without introducing unnecessary sources of error. Standard procedures may also be violated due to insufficient familiarity with prescribed methods. For example, in the cases I review, many experts seem unfamiliar with the precise rules for scoring the Visual Reproduction subtests from the Wechsler Memory Scale-Revised (Wechsler, 1987).

Failure to follow standardized testing procedures can make the psychologist look bad. Take, for example:

> Q: Doctor, you told us that Ms. Smith demonstrated problems in delayed memory, isn't that true?
> A: Yes, there were problems that seemed significant to me.
> Q: And you administered the delayed version of the Fisbee Memory Test, correct?
> A: Correct.
> The lawyer might next ask some questions to help the jury get a clear picture of the test and the way delayed memory is examined. The lawyer then asks:
> Q: And you told us that Ms. Smith scored in the borderline range on the test, didn't you?
> A: Yes, that's a label I used, although her percentile was rather low, at about the 9th percentile, if I remember correctly.
> Q: Borderline is the category between normal and abnormal, right?
> A: I'm not sure I would say it that way, but I would agree with the basic thrust of your question.
> Q: Had she gotten a few more points of credit on the test, the score would have been classified as low average, isn't that true?
> A: That's true, but she didn't.
> Q: And you have already agreed that according to school records, Ms. Smith was functioning at a low average level in a number of areas before the accident, isn't that true?
> A: Yes, but I'm not sure that applies to her memory functioning.
> Q: And one of the reasons you are not sure it applies to memory functioning is because we have no direct pre-accident memory tests, do we?
> A: Well, I think some of the past tests reflect on memory abilities, but it is true I have seen no records of specific memory tests that predate the accident.
> Q: Doctor, let's return to the Fisbee Memory Test that you gave to help determine the possible impact of the accident. Doesn't the test manual state that the delayed version is to be given about 30 minutes after completing the immediate version?
> A: Yes.
> Q: Doctor, do we usually remember things better over a longer or shorter period of time?
> A: Shorter may be better, but not always.
> Q: Doctor, you're not telling us, are you, that if I want to win a bet about when these jurors will remember the most about the trial, I should bet on next month rather than tomorrow?
> A: I don't accept your analogy, and psychological phenomena do not always follow what might be considered common sense.
> Q: So we're learning. In any case, when you administered the delayed version, you did not wait 30 minutes as the manual indicates, you waited 60 minutes instead, isn't that true?
> A: Yes, but I don't think it makes any difference.
> Q: Doctor, the instruction in the manual does not say it's fine to wait 60 minutes, does it?
> A: No it doesn't, but many studies suggest that the amount of memory loss that occurs after 30 minutes and 60 minutes is similar.
> Q: Doesn't the manual also state, and I quote, "The examiner should follow the instructions specified in this manual for test administration exactly in order to ensure proper comparison with the standardization group"?
> A: I can't recall exactly.
> Q: Well, I can show you the manual if you want.
> A: No, that's OK, I'll take your word for it.
> Q: Certainly it is possible, is it not, that a different result might have been obtained if delayed memory had been administered after 30 minutes versus waiting twice as long? (It probably will not matter what the psychologist says.)
> A: It is possible, but I doubt it.
> Q: And doctor, the reason to give the test as the manual specifies is so that we know how the individual performs when the test is given as designed, rather than having to guess how it would have come out if it had been given as the manual instructs, correct?

A: Those are your words.
Q: Doctor, I'm asking you. However, let's just move on. In a sense, doctor, you were measuring her on the 30 yard dash but made her run 60 yards, isn't that true?
A: No, I don't think you can make that comparison at all.
(The expert might think that but the jury is likely to believe that the analogy makes pretty good sense.)
Q: You waited twice as long as the prescribed time, and Ms. Smith obtained a borderline score, which you agreed was just a few points below the low average range, correct?
A: Yes.

I have also reviewed reports laden with factual inaccuracies relating to such matters as level of education, the date of the accident, the number of prior accidents, the number of children the plaintiff has, job history, etc. It may be difficult for a juror to believe that an expert can reach accurate conclusions about things that cannot be directly observed and that are complex—-such as the area in which the brain is damaged or about the inner workings of the mind—if the expert cannot get simple facts straight, such as the day the accident occurred.

4.19.4.4.4 Give adequate consideration to alternatives

Research on clinical judgment suggests that diagnosticians can increase accuracy by waiting longer before reaching conclusions and considering alternative possibilities more actively (Faust, 1984; Faust & Willis, in press). In courtroom cases, the opposing lawyer will often present causal theories or explanations that contrast to those the expert proposed. An expert who has already made a systematic effort to evaluate and consider alternatives is more likely to be correct in the first place and better prepared to defend his position. For example, when the lawyer asks, "Isn't it true that excess caffeine intake can also cause symptoms of anxiety? the response might be, "Although that is certainly true, the chart I constructed of caffeine intake and anxiety levels shows that anxiety levels often were high even when caffeine intake was low." The expert who has not carefully evaluated plausible alternatives might have to admit, instead, that she is not in a position to say whether, or the extent to which, caffeine might have contributed to the clinical presentation. The increased probability of an accurate conclusion also enhances the likelihood of providing true assistance to the trier of fact and may be critical in the examinee's care, whatever the courtroom implications. For example, if the plaintiff's cognitive dysfunction is due to the onset of a schizophrenic disorder as opposed to mild brain damage, very different treatment is likely to be indicated.

(i) Alternative diagnoses, including malingering

Given the overlap in symptomatology across conditions, or the lack of specificity of many symptoms (e.g., anxiety, sleep problems, difficulties concentrating), clinical presentations often raise multiple alternative possibilities that require careful analysis and reanalysis of the positive and negative evidence. The defense expert who is leaning towards adjustment disorder may need to reconsider the chronicity of the condition and the substantial level of maladjustment. The plaintiff's expert who diagnoses PTSD may need to re-examine the absence of physiological arousal and the infrequency of intrusive thoughts. A neuropsychologist who is quick to diagnose a mild brain injury may have mistaken it for a depression that started earlier following disturbing life events. A psychologist who identifies characterological disorder as a basis for what he believes are false or exaggerated perceptions of sexual harassment may need to abandon this conclusion when collateral records for the 10 years prior to the reported events nearly all suggest good adjustment and interpersonal relations. Along these lines, various diagnoses are packed with assumptions about previous functioning, and experts may miss an excellent opportunity to check on their impressions by examining whether records about these periods conform to expectation. For example, someone diagnosed with hypochondriasis, which is usually assumed to be chronic, would be expected to have voiced multiple medical complaints in the past, and not just since the injury 6 months ago. If various past medical records show select, delineated, and realistic medical complaints (e.g., the finger did turn out to be broken when x rayed), it may be time to rethink the diagnosis.

In many legal cases, psychologists should be more complete in the assessment of malingering. For example, they may not collect any collateral information and may limit appraisal of malingering to interview impressions and a single test that the literature shows to have poor sensitivity. I have reviewed many evaluations in which the Rey 15-Item Test (Rey, 1964) was the only measure specifically used to appraise malingering. The sensitivity of this test is so poor that in cases of malingering, it apparently stands a worse chance of detection than a coin toss (see Rogers, 1997a). Other research suggests that it is difficult to detect malingering through typical interview methods and clinical impression (see Faust & Ackley, 1998); and as Ziskin (1995) suggested, when a mental health professional asserts otherwise, the lawyer can ask, "Each time you've been fooled, you don't know it, do you?"

The psychologist who aspires to expertise in legal assessment should have a solid familiarity with the literature on malingering. Rogers' (1997a) edited book is a good starting point in this venture. The literature demonstrates the limits of traditional methods (e.g., interviews, many psychological tests), suggesting that: (a) individuals can manipulate results on a wide variety of tests, and in so doing may fool clinicians into overdiagnosing emotional or cognitive disorder; (b) it may be very difficult to detect face-to-face lies, especially by interview or impressionistic methods; (c) experience by itself does not ensure adequate detection capacities; and (d) the base rates for malingering may be higher than many psychologists believe (but lower than other psychologists believe) (see Faust & Ackley, 1998; Rogers, 1997a). For example, Reynolds (1998) asserts that "reasonable and thorough research indicates that at least 25% of cases of head injury in litigation involve malingering" (p. viii). Familiarity with the "negative" literature on clinicians' detection accuracy using more traditional methods is helpful because it directs us to take additional steps and because there has been such a recent growth in malingering detection methods—alternative or supplemental methods are available. This is a prime example of an area in which recognition of limitations in the field has had a very constructive impact by sparking intensive, productive research efforts.

The MMPI remains the most thoroughly researched test for malingering detection. MMPI indices and methods for malingering detection go beyond such traditional scales as F, L, and K, and are well described in various overviews of the topic (e.g., Greene, 1991, 1997). Differences in application with emotional distress versus brain damage claims are important to recognize, although the MMPI may be of considerable value in malingering detection with both types of cases.

There are also many specialized tests for malingering detection that are at varying stages of scientific development and of varying utility. One such example is forced-choice methods (Pankratz, 1988). Tasks are set up in which the examinee is instructed to select the correct answer from among two or more choices. For example, the examiner may read a string of digits to an examinee, then show her two written strings, and ask her to select the one that she just heard. A delay may be introduced before selections are made to increase the difficulty, or perceived difficulty, of the task. With a dichotomous choice format, even an individual with no memory capacity should achieve about a 50% level of accuracy through random guessing. Some malingerers overplay the role, failing to realize that performance that falls substantially below chance requires knowledge of correct answers. Although such types of forced-choice methods may have high valid-positive rates (correctly identifying malingering when test results are positive), valid-negative rates (correctly excluding malingering when results are negative) are often poor (Rogers, 1997a). There are, however, rapid ongoing developments with this and other specialized malingering detection methods, creating good reason for optimism and making it important to regularly update one's knowledge of the literature.

Interview methods are also available, in particular the Structured Interview of Reported Symptoms (SIRS), developed by Rogers, Bagby, and Dickens (1992). The SIRS uses various detection strategies, the majority of which seem to capitalize on false stereotypes or general beliefs about mental disorder. A variety of studies from independent researchers on a range of topics suggests that the SIRS may have strong properties for malingering detection (see Rogers, 1997b).

Other recent studies have investigated whether knowledge of disorder and knowledge of the strategies that underlie the design of malingering detection methods help the examinee escape detection (see Faust & Ackley, 1998). This research is still at a relatively early stage of development, although it suggests the following tentative generalizations. With testing methods that use something more than the very simple types of detection strategies (like the MMPI and unlike, say, forced-choice methods), knowledge of disorder seems to be of limited helpfulness. In contrast, knowledge of detection strategies increases—sometimes markedly—the likelihood of escaping detection. With typical or unstructured interviews, however, knowledge of disorder may well be useful, and perhaps the most helpful element in successful malingering. If these conjectures turn out to be correct, it seems likely that the chances of detecting better prepared or more sophisticated malingerers may be greatly enhanced by using a combination of specialized testing and specialized interview methods (such as the SIRS), although one must worry about inflating the false-positive error rate. Optimal use of these methods, especially if multiple data sources are obtained, will likely be achieved through the development and application of formally validated decision rules or actuarial strategies for data combination (Dawes, Faust, & Meehl, 1989; Grove & Meehl, 1997; Meehl, 1954). The idea that more information is better may already seem obvious, but considerable research in clinical decision making across multiple areas shows that intuitions about these matter are frequently misplaced and that there are many circumstances in which greater selectivity in data use and combination would result in greater accuracy (see Dawes et al., 1989; Faust, 1984; Faust & Willis, in press).

(ii) Considering alternative causative factors

Assuming a condition (e.g., brain damage or PTSD) is present, the question of what caused it can completely determine the outcome of a legal case, and hence is often one of the forensic evaluator's central concerns. Although some experts depend mainly or solely on self-report to determine cause, even the most honest plaintiff may not know what created her difficulties, or can make inadvertent errors in associating symptoms with events and conditions. If patients always knew what caused their problems they would not need doctors or mental health experts to perform differential diagnosis. Overattention to temporal sequence or focus on a salient event may lead to misattributions, as might faulty diagnoses by other providers. Factors may be operating that the individual could not possibly have been aware of, such as an unrecognized exposure to a toxin at the work site that causes a gradual, delayed reaction. Suppose such exposure leads to insidious decreases in reaction time and coordination, which in turn lead to a car accident that causes a very mild head injury. It is easy to see how causal confusion can arise. In other instances, of course, plaintiffs purposely mislead. This may be very difficult to detect, because their conditions may be real but may have arisen from another cause that they will hide or disguise. The chances of uncovering the deception may depend largely on obtaining sufficient background information.

Assessment results may also stem, in part or in whole, from transient or extraneous factors (for discussion of multiple possible confounding variables in brain damage cases, see Faust, 1995). Individuals are sometimes tested under poor conditions that obfuscate conclusions about more stable impairments. In one case, a nationally known expert, who had been retained by the defense, examined the plaintiff in a room in an airport. He concluded that problems seen on testing probably were not caused so much by the head injury in question but rather by exposure to jet fuel fumes during the examination. In another case, an individual set out very early in the morning to drive the 200 miles to the psychologist's office, and ended up so tired he could not stay awake continuously during the testing. I have even reviewed cases in which examinees told the psychologist that they literally had not slept at all the night before, and yet the testing proceeded. Children are sometimes tested when they are ill and cranky or suffering from ear infections. In other situations, psychologists continue testing for 8 or 9 or 10 hours, and then write a report indicating that one of the plaintiff's main difficulties is rapid fatigability (while maintaining they have obtained "valid" testing results or results that do not underestimate capacities).

Many psychologists have very busy schedules, and cancelling a case slotted for a half or full day can create real headaches, but sometimes there would seem to be no reasonable alternative. Otherwise, the psychologist may have to answer questions like, "Doctor, do you ever tell your patients, before an important examination, to try to stay up all night so that they can do their best?" In contrast, there may be circumstances in which these types of accompanying problems and maladies are stable features of an individual's condition. For example, it might be that the plaintiff's physical discomfort, versus the brain injury, was the greatest contributor to performance difficulties during the examination. However, if the accident caused painful orthopaedic problems that are unlikely to remit, the adverse effects on cognitive performance may well be characteristic and typical of the individual's day-to-day functioning.

The many factors that may cause extraneous or transient alterations in cognitive, emotional, or behavioral status include, to name a few, sleep deprivation, pain, caffeine abuse, alcohol and other forms of substance abuse, medication side effects, and a myriad of independent medical conditions. Stressors and problems separate from the accident may also impact greatly on emotional or cognitive functioning. In situations in which these types of factors may have altered results, it can be very helpful to re-examine the individual at a later time. For example, if there is a question about the relative contributions of mood disorder versus brain injury to performance on cognitive tests, retesting after the depression has been treated successfully may help to parse these factors.

4.19.4.5 Interpretive Strategies

A detailed discussion of interpretive strategies is well beyond the scope of this chapter, and only a few general guidelines will be suggested. Some of these guides may seem obvious and might be best viewed as reminders; I hope they will not strike the reader as too rudimentary. Other guides stem from the extensive literature on decision making, which provides many useful ideas and procedures. The decision making literature often has not infused writings on clinical practice. This is unfortunate because many of these principles, while very helpful, are counterintuitive, even for professionals, and hence are unlikely to be recognized or realized without direct exposure. Introductions to the decision making literature can be found in a variety of sources (e.g., Arkes, 1981; Faust, 1986; Faust & Wedding, 1989; Faust & Willis, in press; Wedding & Faust, 1989).

The recognition that interpretation is unlikely to be better than the data upon which it rests highlights the need for careful collection of information and adherence to proper examination procedures. Prudent data gathering can go a long way towards increasing the chances of reaching sound and defensible opinions.

It is hardly newsworthy to suggest that not all interpretive procedures and available methods are equally sound. Not uncommonly, various procedures are applicable to the same data and lead to conflicting conclusions. For example, there may be five or more procedures for judging cooperation with the examination or malingering, with some pointing in different directions. Further, there may be no simple way to combine or integrate these results, because they may directly contradict one another. If one decision rule indicates that there is brain damage and the other that there is not, both cannot be correct.

Obviously, when all decision rules coincide, there is nothing to resolve, but when they conflict directly, one must select one over the other (or defer judgment). At times this may not be too difficult, because the great bulk of the evidence, especially that of the highest quality, points in a certain direction; but in other cases the results are more ambiguous. For example, what does one do if the single best decision procedure argues for Conclusion A, but two other methods of more modest accuracy argue for Conclusion B, and one is not sure how these latter two methods operate in combination?

In these conflictual situations, a psychologist is much better off, to illustrate a relative extreme (and assuming all other things are equal), if the decision rule given preference has stronger research support, has provided a clearer result, is better suited to the examinee, and, when pitted against the other decision rule(s), has been shown to be correct more often. As the table tilts in the other direction, the chances of being correct decrease and vulnerability to informed and skilled cross-examination increases. These and other issues involved with the combination of data are addressed in such sources as Dawes et al. (1989); Meehl (1973); and Faust (1984) (see also Faust & Willis, in press). As these authors note, considerable research suggests that it is not necessarily best to try to combine all of the data or to analyze complex configural relations. Formal decision procedures (e.g., actuarial methods) that have been developed through proper scientific methods almost always equal or exceed the overall accuracy attained through these types of attempts at subjective or clinical data integration.

Interpretive methods may fail to consider base rates (see Meehl & Rosen, 1955; Wedding & Faust, 1989), or the frequency of events. For example, the accuracy of diagnostic signs and methods varies in relation to the frequency of a condition, and adjustments in the application of such indicators and in estimates of likelihood are likely to be needed as base rates change. To illustrate, as the frequency of malingering decreases across settings of application, the same score on a simulation index signals a lower probability of malingering, and hence cutting scores may need to be raised to avoid an unacceptable false-positive error rate. Along related lines, characteristics that are common among the general population may be described as indicators of pathology. Some such "signs" are part of clinical lore, and their use may not have been modified in accord with research. For example, a psychologist may assert that five points of subtest scatter on the Wechsler Adult Intelligence Scale-Revised (Wechsler, 1981) is indicative of disorder, although research shows that most normal individuals equal or exceed this level (see Matarazzo, Daniel, Prifitera, & Herman, 1988). Given mental health professionals' skewed exposure to abnormal populations, it may be difficult to determine whether features seen commonly among patients are indicative of pathology or rather just common among individuals in general and thus poor discriminators of disorder.

I have reviewed many reports in which pedestrian human failings were stated as self-evident signs of disorder. When supposed pathological features include sometimes misplacing one's keys, occasionally forgetting where the car is parked, and irritability with misbehaving children, a good cross-examiner can have a field day. It is often necessary to consult epidemiological research and associated literature to determine just how often features occur among normal and abnormal populations, and also whether they occur with differential frequency among different forms of disorder. The latter type of knowledge can be essential to differential diagnosis.

Overdiagnosis, or the tendency to see pathology that is not present or to overestimate its severity, may result from various sources. Overestimation of prior functioning may lead to overestimation of changes in functioning. False conclusions about prior functioning may stem from such sources as faulty history that the plaintiff reported or faulty methodology. For example, some psychologists believe that the single highest, or few highest, test scores provide a good estimate of prior overall or general intellectual functioning (the so-called "best performance approach"). Given normal variation in test scores, this method is almost sure to lead to overestimates, and not uncommonly gross overestimates, of prior functioning, especially among unaffected individuals. Given the average seven point spread between the highest and lowest subtest scores on the Wechsler Intelligence Scales (Matarazzo et al., 1988), use of the single highest score with normal individuals will result in an average overestimate of 15 to 20 points in prior Full Scale IQ (FSIQ). The result will be an estimated loss of 15 to 20 FSIQ points in an individual with absolutely no adverse change in intellectual functioning. This might be the difference, for example, between a score near the 90th percentile and one at the 50th percentile. The absurdity of this situation is that, on average, an individual will have to have gained over 15 FSIQ points to be judged to have retained his prior capacities!

Another basis for overdiagnosis is the use of inappropriate norms that set overly demanding performance standards. This problem is especially common when norms are not adjusted for sociocultural and demographic features or test bias. For example, a test may show pronounced age and education effects and yet a clinician, perhaps unaware of these findings, might apply norms developed on young, highly educated individuals to much older and less educated individuals. Also, in at least some normative studies, individuals with virtually any significant risk factor are eliminated from the sample, resulting in supernormal groups, or groups whose performances well exceed the general population (this being one reason why average IQs are often so high in normative studies on various neuropsychological measures). The result can be a mistaken belief that unaffected individuals have suffered a loss attributable to the event in question (e.g., a head injury) because their test performances do not meet the inflated standard set by the "normative" group. This can also lead to the initiation of treatments which may carry risks for target problems that do not exist. Overdiagnosis can also stem from overattention to select weaknesses, insufficient awareness of the overlap between normal and abnormal populations, and failure to recognize normal variations within or across individuals, the latter of which was previously illustrated by reference to subtest scatter on intellectual tests. Normal individuals are rarely unremarkable or well adjusted or well functioning in all respects, and the tendency to conclude that an individual is aberrant due to even minor shortcomings creates a hurdle that few of us would pass.

Other psychologists underestimate or fail to recognize pathology, with explanatory factors sometimes representing the flip side of the same coin that leads to overdiagnosis. For example, psychologists may be quick to assume that problems pre-dated the accident. Weaknesses on cognitive or neuropsychological tests may be attributed to pre-existing learning disabilities, even without checking school records. Emotional problems may be assumed to represent Axis II disorders, and hence characterized as life-long difficulties as opposed to consequences of a more recent accident. In a case in which I consulted involving an individual with a moderate to severe brain injury, a psychologist passed off various potential indications of frontal lobe disorder, such as impulsiveness and marked difficulties with interpersonal relations, as indicators of a borderline personality disorder (BPD). However, this individual also presented with various features unrelated to BPD but positively associated with brain injury, only demonstrated characteristics of BPD that overlapped with those of brain damage, and demonstrated virtually nothing pre-injury to suggest any type of personality disorder.

Some experts are very quick to assume that individuals are malingering and that this explains their symptom presentation. In a toxic exposure case, a psychologist casually dismissed seemingly strong neurological findings as feigned symptoms. Ironically, as it turned out, although the psychologist was likely right that the toxin did not cause a problem, she was otherwise quite wrong: further medical work up yielded a nearly definitive diagnosis of multiple sclerosis and left virtually no doubt that the plaintiff had serious neurologic disorder all along. Underestimations of prior functioning may also lead to missed pathology. Finally, in some cases, experts misidentify chronic or permanent symptoms for transient ones. For example, in brain damage cases, experts may be too ready to assume that all of the plaintiff's problems are due to depression when, for example, the original injury was serious, the individual did not appear to have a low mood when evaluated, depression has fluctuated but impairment has not, and at least some of the observed problems (e.g., perseveration and aphasic errors) are much more strongly associated with brain damage than with depression.

4.19.4.6 Preparing Reports

Reports may or may not be introduced as evidence at a trial. When they are, every word becomes a possible target for cross-examination, and thus they should be prepared very carefully. Although I will leave detailed recommendations about report preparation to others, I do have a few suggestions. First, sloppy reports with factual inaccuracies can create a very bad impression, even if the errors are not substantive. In one case, due to a typographical error and poor notes, a psychologist could not say whether a plaintiff, earlier in life, had fallen out of a rocker or had been struck in the head with a rock. Reports should also strive to provide a balanced representation of the case and of positives and negatives. For example, the report of an expert that repeatedly glosses over negatives that seemingly are evident and should not be ignored may be difficult to defend. Alternatively, the report may contain nothing but negatives. For example, when describing responses on a questionnaire or a depression inventory, the examiner may list only the unhealthy responses. This can become especially problematic when, in fact, the majority of the responses are positive. This creates an easy target for the cross-examiner, to wit:

> Q: Doctor, in presenting before us today, you strive, do you not, to provide fair and balanced testimony?
> Q: In gaining a complete understanding of an individual, strengths can be just as important as weaknesses, isn't that true?
> Q: Interventions or approaches to helping a person often build on someone's strengths, isn't that correct?
> Q: When describing the results of the Method X Depression Inventory, you shared Mr. Smith's responses to three items, isn't that correct?
> Q: Each of these items suggested possible problems, you would agree with that, wouldn't you?
> Q: And each of us, doctor, is something of a mixture of positives and negatives, wouldn't you agree?
> Q: There are 20 items on the Method X Depression Inventory, isn't that right?
> Q: We haven't heard anything about the other 17 responses, have we?
> Q: On item number 3, doesn't Mr. Smith indicate that he gets as much enjoyment out of things as he used to?
> Q: You didn't mention that in your report or your testimony, did you?
> The lawyer than reads five more positive answers, and the expert may make some comment such as the following:
> A: You're only mentioning the positive responses.
> Q: And it would be very wrong to only present one side of the picture, wouldn't it?

Some experts write exceedingly long reports that address many minor or irrelevant matters. Again, every word and every comment is potential fodder for cross-examination, and thus including matters that are really not important to the task at hand is unlikely to be of much benefit and could create a problem. For example, such text might include various factual inaccuracies that can make the psychologist look foolish.

Reports may also include many extreme statements. A good cross-examiner usually welcomes extreme statements or exaggerations, because they create an easier target. For example, in one case, an expert did not just say that one method was better than another, but that there was a general consensus among psychologists that it was not just superior, but far superior to another method. This extreme claim was easy to deflate when literature was introduced by the very author of the test describing its limitations. In another case, a psychologist testified that even a very mild brain injury affects every single aspect of an individual's functioning and existence. Although the case was resolved before trial, in part because this psychologist's assertions were so vulnerable, it would have been a simple matter to confront the witness with the many normal test performances (which were entirely consistent with pre-accident measures) and to ask her whether there was any chance they could have been exceptions to her claim. She almost certainly would have said no, leading to a rapid self-destruction.

The exact wording of reports may be important and lead to unanticipated legal consequences. For example, in one case, an extremely bright neurologist wrote a conclusory sentence that included the phrase, "but for the accident." His intended meaning was that the condition would have occurred whether or not the accident occurred. However, in the legalistic world of the arbitrator, the conventional interpretation of this phrase was to the contrary, thas is, that in the absence of the accident, the condition likely would not have occurred. It is generally much safer to stay away from legal terminology unless it is necessary and one understands exactly what one is doing, and rather to just say things plainly and clearly. The wording of a report should also be checked carefully to avoid unintended meanings or interpretations, although it may be possible to clear these up at deposition or trial without creating a problem.

4.19.5 LAWYERS' STRATEGIES AND TACTICS

When dealing with adverse expert testimony, the lawyer's most basic task is to undermine credibility. Some lawyers will attempt to do this with a scalpel and others with a blunt stone, but the aim is the same in either case, and it is to the witness's advantage not to forget it.

Although an attack may be directed at personal matters (e.g., bias, financial incentives), this is often merely part of doing business and reflects nothing personal. The same lawyer who attempted to paint the witness as biased or incompetent may shake hands on the way down the courtroom steps and tell the expert he thinks she did an excellent job. On the one hand, most lawyers do not act in a blatantly hostile or obnoxious manner because they believe their case is best served if the jurors like them. A scowling, hateful, and abusive manner towards a witness, especially one who has done little or nothing to provoke it and who acts in a perfectly civilized and seemingly impartial manner, can hurt the attorney much more than the expert. For an expert who might be a bit thin-skinned, it can be helpful to perform a little personal Albert Ellis and tell oneself that such personal attacks often stem from a position of weakness and do not provide true commentary on one's human worth. A lawyer who is really loaded with ammunition may well prefer to take on an almost pained and solemn expression when bringing to light terrible problems with the expert's work (so that the jury does not end up feeling sorry for the doctor). On the other hand, arrogance and unwillingness to admit obvious points, and other similar demeanor may leave the jury hoping that the expert gets what he deserves and may give the lawyer license to deal out punishment. Obvious lack of preparation can also quickly alienate a jury.

If the lawyer is particularly successful in weakening an expert, she may then introduce materials and questions that are not so much intended to damage the expert's credibility further, for that job has already been accomplished, but rather to put on her own side of the case. For example, rather than the attorney attacking the credibility of a plaintiff directly, which, if overdone or too aggressive, could inflame a jury, it is often safer for an attorney to do so through an opposing expert. The lawyer might raise inaccuracies in the plaintiff's report to the expert that seem purposeful and self-serving. A weakened expert is often fairly helpless against adverse, or seemingly adverse, evidence; and it can have a much greater impact for the attorney to introduce affirmative elements of her case through an opposing, rather than her own, witness. One might consider the effect when the opposing expert cannot fend off attacks on the plaintiff's credibility, versus the dubious impressions that can arise when the plaintiff seems credible and the plaintiff's experts, who vouched for the plaintiff's honesty, were not really questioned on this score. Rather, the first person to raise serious concerns about truthfulness just happens to be the expert the attorney hired.

Cross-examination often does not follow the contour of the expert's direct examination. Although, in some jurisdictions, cross-examination is supposedly restricted to the content covered in direct, in practice it is usually a relative free-for-all with few topics off limits. Further, a good cross-examiner rarely wants or needs to return to the points the expert covered tit-for-tat. Rather, the attorney is selective, looking for weaknesses or vulnerabilities. Many lawyers would much prefer to win a cross-examination 3 to 0, rather than 10 to 2. This is one reason experts should aspire to avoid weak components in their assessment batteries or procedures.

The areas of cross may or may not touch on any of the points covered in direct. In one case, a plaintiff's neuropsychologist had already admitted on deposition that during his entire professional career he had never concluded with relative certainty that someone was not brain damaged, nor had he ever directly identified someone as malingering. He further admitted that in the instant case, he had presumed that the plaintiff was brain damaged nearly from the start, based solely on the very limited (and seemingly far from definitive) information he received at the time the referral was arranged. It would not matter very much what that expert said during his direct, because the lawyer was going to come back to these points, drive them home, and then stop, leaving the expert in shambles. In fact, a lawyer often is able to prepare a cross-examination without thinking all that much about what the expert will say on direct. Rather, the lawyer may consider the gist of the expert's testimony, and then focus most of her attention on the underlying bases or evidence for conclusions and on matters minimally related to the specific content of the direct.

Points of attack, to be covered in order, may include credentials, bias, flaws in the conduct of the examination, questionable conclusions, and weaknesses in scientific underpinnings. Again, almost all of these subjects come back to the expert's credibility. Many lawyers would rather stay away from scientific topics, but others are well prepared to enter this arena. Experts may be accustomed to getting by with cursory or questionable answers to inquiries about underlying scientific methods or potential scientific weaknesses, and may be shocked the first time they confront an attorney who starts asking very specific questions about one or another line of research and will not settle for incomplete or vague answers. Some experts have permanently damaged their credibility by placing on record a host of patently wrong answers to questions about science. The result is the appearance of incompetence or, even worse, dishonesty. I have read more than a few transcripts with claims such as the following: Basic psychometric principles that apply to psychological tests are not relevant to neuropsychological tests; there is no type of board certification in psychology; the (you name it) battery is nearly 100% effective in diagnosing brain injury; there is an absence of research showing a limited relation between experience and accuracy, and so on.

4.19.5.1 Credentials

As discussed, most experts have credentials that sound impressive to a jury. For example, completing a doctoral dissertation, receiving an advanced degree, and publishing (at all) are likely to be viewed favorably. More advanced accomplishments are not likely to make much of a difference. It is ironic, then, that some experts will puff and inflate, or even distort, small points that a juror is likely to find unimportant or trivial. As illustrated earlier in the cross-examination exchange on graduation from an accredited program (see the heading, "Admissibility"), these little points can expand into disasters if they are discovered, especially if the expert will not yield in the face of obvious contrary evidence. It is not unusual for attorneys to conduct background checks and to obtain information about an expert's credentials and past experiences.

4.19.5.2 Bias

A cross-examiner may start by asking the expert whether he endorses the scientific method, and whether it calls for impartiality in examining data, including fair consideration of evidence for and against a proposition. It is difficult to imagine an expert answering negatively to inquiries of this type. The lawyer may then try to show that the expert failed to live by such principles in the present case, or was not even-handed in considering and presenting evidence.

Some reports overemphasize or overattend to either the good or the bad, and may thereby make it easy for the lawyer to demonstrate bias. For example, an expert may list only the positive responses on an anxiety inventory. The lawyer might start reading the negative responses and after each one merely ask the expert, "Did I read the item correctly?" Alternatively, the expert may use dramatic terms and more lengthy narrative to describe weak cognitive performances, while downplaying, or even ignoring, strong performances. Problems may be referred to as "deficits," "impairments," or "serious shortcomings," but a remarkable performance is described as "essentially within normal limits."

Bias may also be suggested when experts fail to conduct sufficient investigation of alternative explanations for results. For example, an expert who quickly decided that the accident caused a brain injury may have been superficial or incomplete when looking into substance abuse as a possible alternative cause for reduced cognitive efficiency, despite records containing various suggestive references. Or, in a PTSD case, the expert may have made a perfunctory attempt to uncover and analyze other potential stressors. If the lawyer can show that alternative explanations were plausible but not pursued with anything approaching the zealousness displayed for the favored explanation, it can create a very negative impression.

Other experts come across as biased because they will not concede the obvious or will not give ground, even when they should. Similarly, some experts strike jurors as evasive. In one case in which I consulted, it was blatantly obvious that the plaintiff's signature was much poorer when produced at the psychologist's request then it was when he signed checks and documents in the course of his everyday life. When the lawyer merely asked, "Do these signatures appear to be of different quality?" the expert would not concede the point. This allowed the attorney to keep reframing the same basic question in a way that made the expert look increasingly outlandish, e.g.,

Q: Isn't there a clear difference in the quality?
Q: Isn't there some difference in the quality?
Q: Do these different signatures look exactly the same to you?

The lawyer concluded the cross by stating, "Doctor, what would you say if I asked you ... ah, never mind, I know what you'd say." Although there may have been a perfectly reasonable explanation for the difference in writing quality (e.g., the plaintiff was heavily medicated when seen by the psychologist), the expert's stubborn adherence to an unsupportable position convinced the jury that nothing he had said before, and nothing he might say after, was worth a second thought.

Other ways the lawyer might try to show bias include financial incentive (e.g., the expert charges much higher fees for legal than clinical work, or has performed numerous legal evaluations with the same attorney), or systematic error that consistently favors the expert's position. For example, a defense expert may have repeatedly overcredited a plaintiff on cognitive tests, thereby underestimating loss in functioning.

4.19.5.3 Manner of Conducting the Examination

Examination procedures have been covered at length previously and will not be repeated here. Errors of omission and commission can create easy fodder for attorneys and can lead to a complete disregard of the expert's testimony.

4.19.5.4 Erroneous or Questionable Conclusions

Erroneous conclusions can stem from various factors, such as mistakes in the scoring of tests or misapplication of scientific methods. In many instances, the correct answer is not cut and dry, and it may be difficult to show, conclusively, that an expert has made an error. Considering, however, the selectivity of cross-examiners, if even a few instances of clear-cut errors on nontrivial matters can be identified and brought out, it may greatly reduce the expert's impact. Concrete facts often provide the lawyer with the best opportunity to find such occurrences, and the search may be greatly facilitated if the expert's review of records has been incomplete or careless.

I have reviewed many cases in which, for example, an expert did not confirm educational level. For a neuropsychologist who adjusts most or all test scores in relation to education, this may lead to erroneous results on almost all measures. It can be difficult for a witness to regain his equilibrium with cross-examination surprises of this magnitude, especially if the normative tables are back at the office. I have also reviewed many cases in which the expert had taken a very limited occupational history. The psychologist might have testified that the plaintiff had never been fired from a job and had achieved a certain level of earnings, when work records show that these assumptions are plainly wrong. Many lawyers are careful in collecting and reviewing facts, are attuned to incomplete or faulty factual renditions, and are capable of using such material to raise challenges, that is, they are much more at home with this type of subject matter than with psychological concepts and research. An attorney is likely to be considerably more comfortable and effective arguing about former earnings than about whether the subject-to-variable ratio was sufficient to conduct a multivariate analysis.

Experts sometimes present conclusions that sound just plain silly or out of touch. For example, they may make a great deal out of normal human failings or overlook obvious, everyday explanations for events. I have read many reports in which supposed deficits are illustrated through examples that apply to most anyone, e.g., difficulty getting organized for a vacation, occasionally forgetting the exact day of the month, or a tendency to fatigue by the late afternoon (this in a person with a hectic job and four children). Financial incentives in cases may be too readily dismissed, or not acknowledged as potentially relevant. For example, a plaintiff who complains bitterly about problems but who has complied with almost no treatment recommendations, even those involving minimal effort and possible discomfort, may be described as giving no thought to the legal case and only wanting to get better. Some psychologists are so used to thinking in complex and abstract ways that they tend to overlook more common or seemingly mundane considerations. At other times, experts may fail to think through the implications of presumed problems or deficits, and whether the kinds of things one consequently expects to be present in the plaintiff's everyday life and lifestyle are present and those that seemingly should not be present are not present. For example, if an individual really has a severe problem with hostility and impulse control, it is doubtful his hunting buddies would continue their monthly get togethers at the cabin. Or, if the plaintiff really develops excruciating headaches when exposed to noise, one would not expect her to join a rock band. Everyday activities that fly in the face of the expert's conclusions can be decisive with juries.

4.19.5.5 Scientific Status

An attack on scientific status might be broad and aimed at the field in general, or narrow and more specifically targeted at the particular methods used in the case. Many lawyers shy away from challenging scientific foundations, but others have little or no hesitancy to do so, are conversant with the issues, and have retained a consultant to help them prepare. Further, unlike cross-examination, deposition inquiries about scientific status carry little risk, and helpful admissions or responses to even a small minority of questions may satisfy the attorney's eventual and basic purpose—to reduce or vitiate the expert's credibility at trial. An attorney may spend 2 or 3 hours asking many questions about the expert's methods and scientific backing, and then, at trial, focus on the one or few areas of questioning in this domain in which she feels she can make the most headway. Again, effective cross in just a few areas can inflict more general damage. Thus, other then wasted time and expense, it matters little if only one in three, or one in five, or one in ten areas of deposition questioning about research will be used at trial.

An expert makes the lawyer's search for damaging material on science much easier if she uses poor methods, lacks basic familiarity with pertinent research, makes grossly overblown claims, will not concede limitations that are well established in the literature, or repeatedly guesses when she is not sure about answers to questions. Much like certain forms of the martial arts, many points about science would probably carry little impact with the jury if experts did not take actions that gave them strength. Suppose, for example, there are a few negative studies on some otherwise well-supported method for appraising malingering. If asked, the expert could say, "Although most of the literature on the method is positive, one has to use it with some caution because isolated studies have not been supportive." However, on deposition, the expert might have argued that the literature is uniformly supportive. Once receiving that answer at the deposition, the lawyer may have nudged the expert out further and further on a limb. For example, the lawyer might ask about the importance of maintaining familiarity with literature on the methods one uses, how negative literature can bring a proposition into question, etc. Then, at trial, the lawyer can wave around the negative studies that the expert denied existed and recite the names of authors that the expert separately acknowledged as authorities.

As discussed, selection of the strongest possible methods is important not only in dealing with cross-examination, but in maximizing the chances of reaching correct conclusions and thereby fulfilling the presumed prescriptive (i.e., normative) role of a courtroom expert, to assist the jury in its deliberations. If there are no adequate methods available, or if the best available methods are questionable, the expert might decide not to undertake the assignment at all. Also, as noted, post-Daubert many courts are placing methods under increased scientific scrutiny and eliminating those found wanting.

4.19.6 DEPOSITIONS AND TRIAL TESTIMONY

As part of the discovery process, most states allow attorneys to depose opposing experts in order to learn what opinions they may express at trial and the underlying bases for their views. Attorneys vary greatly in their approaches to depositions, and the type and position of the case may dictate strategy. Some attorneys play dumb, ask many open-ended questions, and try to get as much helpful material as they can while revealing as little as possible about their trial strategy and anticipated lines of cross-examination. Their aim is to surprise the expert at trial. Others are far more aggressive and ask pointed, challenging questions that are intended to inflict damage, even should the element of surprise be reduced. If the case is almost certain to go to trial, many attorneys will take a more guarded posture, trying to save their best material for the cross. If it is a case the attorney wishes to settle, the deposition style may be more aggressive and aimed at showing the other side that its expert has problems and that monetary demands or offers need to be adjusted. Many cases call for some type of strategy in between, for example, one that exposes weaknesses in a few areas to convey a message that might aid in settlement negotiations, but that reserves some or most of the material for cross should the case go to trial.

4.19.6.1 A Sampling of Deposition Topics

Although the supposed aims of a deposition may be to uncover trial opinions and their bases, the attorney often already has a very good idea what conclusions the expert will express, especially if a detailed report has been prepared. For instance, basic elements of PTSD cases are frequently similar, e.g., that it was the event in question that caused the disorder, that a decrease in level of functioning resulted, and that the plaintiff was essentially forthright and cooperative during the examination. The attorney's main deposition aims will probably lie in other areas, and the scope of questioning is often wide ranging.

Although many experts prefer to talk in more general and abstract terms (e.g., this is a serious case of PTSD that has caused substantial distress and diminished functioning), many attorneys prefer to talk in more specific and concrete terms. In the area of damages, they want to know specifics. What is it exactly that the plaintiff can and cannot do? How long will therapy need to continue and at what frequency? Does the expert have an opinion about work capacity and about diminution in earnings? Exactly which problems can be attributed to the event and which pre-dated it? For problems that have supposedly been exacerbated, what is the precise extent of the change? Some psychologists become unnerved by these types of questions and react in ways that become problematical at trial. For example, they may fail to admit uncertainty, speculating about specifics that can be shown through concrete example and evidence to be wrong.

In addition to specific elements of damage, some of the topics that the expert can expect a well-prepared attorney to cover on deposition in a serious case can be discussed in turn. The attorney is likely to ask the expert about all her sources of information and when they were obtained. The attorney will probably request that the expert bring her complete file to the deposition, and may go through it document by document, asking when each was received. The attorney may also raise questions to determine who controlled the flow of information, e.g., did the expert request the document, did the attorney send it on his own, or did the plaintiff provide it? This type of questioning may translate into lines of cross-examination aimed at showing either that the expert formed opinions early and absent critical information; that the expert never has reviewed key documents; or that the lawyer, rather than the expert, determined what materials the expert reviewed. Further, knowing what documents the expert has not seen can give the lawyer a decided advantage. For example, if the attorney, but not the expert, knows that the plaintiff misrepresented her educational and occupational history, this can lead to embarrassing problems at trial.

As discussed already, the psychologist should not assume that the attorney who retained her will provide all relevant documents, or that it matters little when records were reviewed. Attorneys may not know which of the available documents an expert might want to see, or what new materials an expert might want to obtain. Some attorneys try to contain costs by limiting an expert's access to records or, in some cases, prefer to withhold certain documents for fear of their impact, hoping that the case will settle or that it will not create too big a problem at trial. Also, if a conclusion is reached weeks, months, or years earlier, and the expert does not review potentially critical documents until the eve of a deposition or trial, it can look very bad, especially if treatment recommendations had been issued. How can the expert explain why it took until 1997 to review documents that were available in 1994 and that may have altered the diagnosis and treatment recommendations? Additionally, on deposition, the opposing attorney commonly asks the expert whether he plans to do anything further on the case before the trial, and requests that any changes in opinion be disclosed. (Some jurisdictions require amended reports if new or altered opinions are to be introduced as evidence at trial.) This puts the expert in a very difficult position if he plans a last minute review of documents he should have examined much earlier.

The attorney may also ask whether any literature was used or consulted in the case. If the response is positive, detailed questioning may ensue. Some attorneys will ask knowledgeable questions about such matters as norms, reliability, and validity. Related questions may be asked about the specific assessment methods used in the case. For example, for the various tests the psychologist administered, the lawyer may want to know what normative standards were used, whether other norms were available, the basis for selecting one set over another, what results would have been produced with other norms, and whether the norms contained demographic corrections. The expert might also be asked about the existence of literature that raises questions about her assessment methods or demonstrates limitations in their use, and whether each method is supported by a body of research on accuracy or validity. Again, a positive response may be met with numerous specific questions, such as what studies exist and who published them; whether they involved the exact same methods, populations, and questions; and whether there is contrary literature. With questioning such as this, inaccurate answers or overblown claims, rather than concessions about relative weaknesses, often cause experts far greater problems at the time of trial.

An attorney usually cannot introduce literature during cross-examination unless the opposing expert has acknowledged it as authoritative or as something he relied on in forming his opinion. (The attorney may still have the option of introducing that literature through his own expert.) Generally, the lawyer wants to find out at deposition whether the needed acknowledgement can be obtained, because it is highly preferable to know what is feasible in advance of trial and plan accordingly. Discovering at trial that an expert will not acknowledge an article that was to serve as the centerpiece of a cross-examination may leave the attorney on a bridge that just lost its undergirding. Once an expert acknowledges an article as authoritative at deposition, there is usually no keeping it out at trial, even if the expert tries to backtrack. For example, should the expert say at trial, "Based on subsequent reading I no longer view that publication as authoritative," the lawyer can still refer back to the acknowledgement at the deposition and will probably be allowed to introduce the article and ask questions about it.

Some experts, due perhaps partly to uncertainty about the legal meaning of "authoritative" and because they wish to appear widely read, acknowledge a great range of literature as authoritative or provide very general endorsements. However, in the legal arena, authoritative means, in effect, that the expert defers to the source or considers it worthy of attention. This type of definition should be kept in mind when answering deposition questions about what is authoritative. Thus, for example, unless an expert believes that every article ever published in a particular journal is the definitive word on a topic or somewhere in this arena, it is probably a mistake to endorse that journal as a whole as authoritative. Rather, one might say something like, "The X journal contains a number of strong articles and others I do not think are as good, and I would really need to know what article or articles you are referring to in order to tell you whether I think they are authoritative or if I relied on them in this case." It is also reasonable to say that one respects a certain author, although one does not necessarily agree with everything the writer has said, and would need to know specifically what the attorney is referring to in order to answer a question about authoritativeness or possible use in the case.

Other experts will go to the other extreme, denying that anything is authoritative. Such experts can make a poor courtroom impression because they come across as pushing the view that there is only one person worth listening to on a topic, themselves naturally; jurors tend not to like individuals who act like self-appointed, self-anointed know-it-alls. Also, the lawyer often can still ask general questions about the literature that incorporate the gist of the findings, such as, "Isn't it true there are many studies showing (something contradictory to what the expert has described)? The lawyer might hold up a stack of articles to convey the impression that the assertion about the literature did not emerge from thin air. The expert may not acknowledge the authoritative status of the literature or the findings, and hence the lawyer might not be able to get further, or much further, into the specifics of the particular work. However, the lawyer has been able to bring the findings to the attention of the jury, and the expert's repeated rejections of contrary literature can create a strong suggestion of bias. The cross-examiner also has the option of putting on her own expert, who can acknowledge the existence or status of literature the opposing expert has denied. Finally, it is almost always possible to get certain literature introduced through one or another means. For example, the lawyer will almost always be permitted to ask questions about the manuals for the tests that the expert used.

The attorney will probably ask whether the expert has talked with anyone about the case. If the answer is affirmative, questions will almost surely follow about the identify of the other party or parties and what specifically was discussed; and the attorney might decide to depose one or more of these individuals to get their descriptions. For example, if the defendant psychologist in a malpractice case talked to his supervisor, that supervisor may well be deposed.

The attorney may conduct thorough questioning about credentials. The expert may be asked about courses taken in graduate school, whether an APA-approved internship was completed, and if the expert pursued a post-doctoral fellowship. Questions may also be raised about supervisors and their qualifications, any malpractice claims or ethics complaints, performance on the licensing examination, continuing education activities, and board certification. There are also likely to be questions about research activities and publications. Some experts exclude publications from their resume that might be embarrassing, which tends to make things worse if the attorney uncovers them.

Attorneys frequently ask about fees and fee arrangements, and how charges for legal work compare to those for other activities. In some cases, experts insist that an evaluation was conducted primarily or solely for clinical purposes, but have billed at the much higher rate used for their legal work. The expert may also be asked how often she has been retained by the same attorney in the instant case, and by the attorney's firm, and perhaps what percentage of her income comes from these cases or her legal work in general.

The expert should be cautious about circumstances in which she is unlikely to be paid unless "her side" wins. For example, an expert may have a multi-thousand dollar fee outstanding with an impoverished plaintiff. A cross-examining attorney can bring out the situation and ask the expert whether these financial arrangements might make it difficult to be fully objective. The lawyer probably will care little about what the expert answers because the seed has been planted in the jury's mind, and an expert who denies such a possibility might well appear to be showing the very bias he denies he manifests. It is thus often advantageous to have at least an understanding, if not a written agreement, that the attorney who retained the expert will be responsible for fees (although deposition time will usually be covered by the opposing attorney).

Experts may also be asked about possible alternative explanations for reported problems or difficulties, evidence that might exist for and against each possibility, and the process they followed in making their selections. They may be asked what type of evidence could be uncovered that might alter their selections or opinions. If the expert has not been thorough in reviewing background materials, the answer may contain elements that, in actuality, are present in the file. For example, suppose the expert answers that narcotic abuse could produce the symptoms he observed on his examination, and that the main way of distinguishing this possible cause from the one he identified is temporal sequence or association. It might just be that the plaintiff had obtained prescriptions for pain-killing narcotics from three separate doctors, was filling them simultaneously, and that the alterations the expert described started 3 months after the accident but just days after the visit to the last pharmacy.

The expert may be asked to critique the work and opinions of other experts, including those on her own side of the case. Sometimes the idea is to link a strong expert with a weak one, creating considerable difficulties for the former when the latter fares badly. If the expert says he endorses another expert's work completely, he had better be prepared to live with the approval not only in the present case, but perhaps in future cases as well. For example, failure to criticize weak methods when asked about views on the other expert's work may translate, in effect, into tacit endorsement, which can be brought up again in the next case and may also lead the expert into contradictory positions.

4.19.6.2 Some Suggestions for Depositions

Perhaps the most obvious suggestion, and one that applies similarly to depositions and cross-examination, is to prepare thoroughly. The required preparation varies and may include a review, or re-review, of the case records, relevant scientific publications, and, perhaps, test manuals and related materials. With large files, it would not be unusual to need a half day to refamiliarize oneself with the case, especially if it has been laid aside for some time, and for very large files, a full day might be required. With more complex files, constructing a time line or chronology that summarizes major events or findings can greatly reduce the time that is needed to become reacquainted with the details at a later date.

It is usually sensible to meet with the attorney with whom one is working in advance of the deposition. If not already accomplished, the attorney needs to gain a clear understanding of what the expert can and cannot say, the boundaries of the expert's opinions, and what materials have been reviewed (e.g., the expert may have examined literature on his own that was not part of the attorney's case file). The expert also may need to be informed about particular technical or legal issues. For example, certain materials may have been excluded or deemed inadmissible and should not be referred to when discussing opinions. The expert may also benefit from learning something about the opposing attorney. For example, some attorneys may try to be especially provocative during depositions, hoping the expert will respond angrily and say something foolish.

If a lawyer is not interested in a pre-deposition meeting, it might be time to start wondering about the attorney and the situation that the expert might have gotten himself into. Similarly, the attorney needs to allow (and be willing to pay for) adequate preparation time. For counsel, this is likely to be one case with one expert, and the attorney's more basic obligation is to the client; for the expert, most every case becomes part of his "permanent record." The attorney is unlikely to lose the next case because her (now abandoned) expert in the previous case was trounced, but the consequences for the expert may carry across cases and years. Some experts, however, go overboard, spending too much time on minor or secondary issues or requiring inordinate amounts of time to prepare for depositions. It is hard to say exactly where to draw the line, and matters become much more difficult if disagreements about how to handle and prepare for a case arise late. If the expert feels that the attorney is setting restrictions that compromise professional standards, and if this situation is understood from the beginning, she can turn down the case as outlined. Alternatively, the attorney can be told what limits this could place on the soundness of opinions, and that any such shortcomings would be openly conveyed on a deposition. The attorney can then decide whether to loosen restrictions or retain someone else, the latter option sometimes being best for both parties.

Deposition questions, especially those that are well articulated, frequently call for specific answers and not dissertations. For example, if the attorney asks, "What is contained in your file?" or, "Did you consult any scientific literature when working on this case?" an exegesis on the state of psychology is not required. It is often unwise to answer vague, unclear, or overly general questions. For example, the attorney may ask, "Do you believe Smith suffered a head injury?" It may be impossible to tell whether the question refers to any type of injury to the head (e.g., a facial laceration), or specifically to the brain. If one goes ahead and answers "yes," an attempt at trial to explain that one thought the question referred to any type of head injury, and not solely to a brain injury, may fall on deaf ears (assuming the expert ever gets a chance to attempt an explanation). Responding to overly general questions can cause similar problems. For example, the attorney may ask, "Isn't it true that individuals with PTSD show difficulties with interpersonal relationships?"

When problematical questions are raised, one can simply say that the question is difficult to answer as stated and explain why, e.g., " ... because the answer differs depending on the specifics." If the question was not worded artfully but the expert thinks she knows what was intended, it is reasonable to respond with something like, "I understand your question to mean .... Assuming this, then ..." The lawyer, of course, can stop the expert if the rephrasing distorts the intended meaning (although he might prefer the question the expert has created over his original one).

Sometimes single or seemingly small changes in wording can ruin a question. For example, the lawyer might start by asking, "Is it fair to say that post-traumatic stress syndrome ...," and one might not know if the reference is to the formal diagnostic category or to symptoms that can follow trauma. Depending on which meaning is intended, the answer can change entirely. There is often nothing wrong with explaining what the ambiguity is and why it may be important to clarify the exact reference; and usually a good attorney can quickly discern whether experts are trying to be cooperative and are requesting needed clarification, or rather are being difficult and evasive.

Although it is important to listen to questions very carefully to be sure one knows just what is being asked and to determine whether the question is answerable, one can go too far and make the process miserable for everyone. It can be very difficult for lawyers who are not expert in an area to ask questions with a high level of technical proficiency and exactitude. As long as the question is clear or the expert, through rephrasing, can check to make sure the question is understood (with this assumed meaning memorialized on the record), it should be possible to answer. The relative ease with which a deposition proceeds can depend in large part on the rapport between the opposing lawyer and the expert. If the lawyer is constantly rephrasing answers, attempting to get the expert to endorse a distortion that supports some contrary argument, or if the expert is really being nonresponsive in order to evade the import of questions, the whole process can bog down and become cumbersome, to say the least. If, however, the lawyer is doing his best to be clear and the expert her best to be responsive, and if the two can cooperate in clarifying ambiguities in questions, the process will usually go along reasonably.

The lawyer who has retained the expert will sometimes ask her to approach depositions parsimoniously, restricting herself to the question asked and volunteering no additional or extra information. As a somewhat hyperbolized example, if the lawyer asks, "Did you do anything to confirm allegation A?" the answer is, "Yes," not, "Yes, what I did was ..." Other lawyers will ask experts to answer more fully. They may fear that areas of testimony will be blocked if, upon questioning, opinions and their bases are not adequately explicated. For example, if cursory answers are provided to questions about the literature the expert relied on, she may be prohibited from discussing that literature at trial. After all, a fundamental purpose of a deposition is to learn the underlying bases for an expert's opinion, or to avoid courtroom surprises, so that the opposing lawyer can prepare for trial. Other lawyers want more complete answers because they hope or expect that a show of strength will give them settlement leverage.

Whatever the response style adopted, it is questionable to avoid an answer by exploiting trivial technical problems with the wording when the expert really knows what the opposing attorney is asking. I attended one trial in which an expert was asked, "Is there board status in neuropsychology?" The context of this question almost surely made it apparent to the expert that the lawyer meant board certification. However, because the lawyer did not ask the question exactly right and the expert wanted to avoid losing ground, the response was, "No." Aside from such a response style being disingenuous and arguably obstructing the legal process, getting caught can be costly. In the case in question, during a break, the lawyer recognized his mistake. He went back and made it very obvious to the jury that the expert had known exactly what the attorney was asking and had avoided answering on a technicality. This made the answer hurt 10 times more than it ever would have had it been surrendered earlier. Those less familiar with the trial process may be surprised by the magnitude of the consequences that can follow when an expert is caught in an intentional misrepresentation, whether it is a direct lie or the offspring of evasion.

Uncertainty about the answer to a deposition question should be readily conceded. One cannot know everything, and such a concession is usually far less injurious than a wrong guess, or repeated wrong guesses. Lawyers may try to bait experts by insinuating in some way, perhaps simply by tone of voice or suggestive words, that they are asking about something that is very basic and that any professional would be expected to know. "Doctor, are you familiar with the large number of studies on . . .?" "Isn't one of the most frequently demonstrated findings in your field . . ." The lawyer may be hoping that the expert will make guesses, because with each guess there is an increased risk of error. If an expert guesses 10 times and is wrong three times, it is not hard to anticipate which three topics will be raised on cross-examination. The expert should not feel that she has to be absolutely certain about everything she utters in a deposition, but if the level of uncertainty passes some relatively low threshold, it might at least be noted (e.g., "If I remember right . . ."), or one should just say that one is not sure and does not want to hazard a guess. (Of course, if these types of uncertainties apply to opinions, and especially if the expert is merely guessing or almost tossing coins, he probably does not belong in the courtroom in the case; and one hopes the attorney who has retained him will not learn about this for the first time during the deposition.) Similarly, it is extremely risky (and potentially unethical) to make some claim that cannot be supported, e.g., "Despite the many negative studies on experience and accuracy, there are far more studies showing a positive relation between the two."

Depositions require a high level of concentration and can strain endurance. If one is too tired to pay close attention to questions, it is at least time to take a break, or to call a halt to the process. Stopping can be cumbersome if expensive travel arrangements are involved, but poor answers on depositions can destroy cases and haunt experts for years, or forever. Experts also should not let their guard down, something that is more likely to occur with fatigue. An off-handed comment on a break may be the first topic raised when the deposition is resumed. It may be particularly hard to maintain vigilance with a highly personable, friendly attorney. Whether or not the attorney is an honest, good-willed, considerate, and kind individual, her job is to win the case and she is likely to use anything she can (within professional ethics and the law) against the expert. Thus, at least within the context of the litigation, that attorney may best be thought of as someone for whom you are the enemy.

Lawyers will sometimes spring new sources of information on experts during depositions, such as publications, medical reports, or documents relating to the plaintiff's everyday functioning, such as work records. If one is unfamiliar with the material, it calls for an open admission. If the lawyer wishes to ask questions, the expert should request the time needed to review the material. If it is not possible to perform an adequate review on the spot, the deponent should so indicate. Alternatively, if the expert believes she has acquired a reasonable grasp of the new material, she might state on the record that she will try to be helpful by answering questions about documents that she has just seen for the first time, although upon more careful study and reflection impressions or conclusions might change. Keep in mind that new materials might be presented out of context, which can lead to misimpressions. For example, one may come to learn that a letter describing insubordination as a basis for termination was written by a boss subsequently arrested for criminal behavior that endangered the public, and that it was the plaintiff who had heroically reported the misdeeds.

4.19.6.3 Trial Testimony

Prior to trial testimony, as with depositions, the expert typically should meet with the attorney. The meeting can address the topics to be covered on the direct examination and what might occur on cross-examination. Once again, the lawyer needs to understand what the expert can and cannot say and any reservations and uncertainties pertinent to the expert's views. Almost any attorney would want to know about these limitations and problems in advance, preferably as soon as possible, rather than discovering them during the expert's cross-examination. In one case, an expert testified that the plaintiff would have developed a particular disorder whether or not an accident had occurred. What he did not tell the attorney that retained him was that he believed it may have taken as long as 10 more years for the condition to develop if the traumatic accident in question had not occurred, something that came out at the end of the cross-examination. Had the lawyer known about this qualification in advance, he would have offered considerably more money to settle the case.

For each topic to be covered on direct, the lawyer needs to be able to ask the expert a question, or questions, that permit entry into the subject matter. If a sufficiently precise question is not articulated, the expert may not even understand what the lawyer is asking, or may have no way to connect the question to the intended material. The lawyer can try out questions in advance to see if they prove sufficient to elicit the intended topic. An expert also needs to prepare for the possibility that upon objection, the judge may preclude queries or entire lines of questioning, which again emphasizes the need for expert and attorney to have a good idea about the topics to be covered. If the attorney does not really have this appreciation and is operating more by rote, unexpected alterations in the direct due to a judge's rulings or small slip-ups can be extremely disruptive.

Like a decent lecture, testimony is usually more effective if it is straightforward, accessible, unfettered with needless and endless complications, and not too lengthy. The jury may already have had a long day by the time the expert goes on, and, often, the expert's testimony is just one piece, although perhaps a crucial one, of a much larger composite that may include long strings of witnesses and days of evidence. A complex, obtuse, and exceedingly detailed presentation may quickly bore the jury and lead to inattention. This is not to argue for glossing over crucial points or simplifying at the cost of distortion. It is often very important to present the underlying bases for opinions, rather than just the conclusions, and in some instances detailed analysis and explanation are needed. For example, when discussing the use of a psychological instrument in malingering detection, a relatively detailed description of scales and their rationale may be necessary. Nevertheless, careful analysis will show that in most cases one's testimony revolves around only a few major points, many details are not of particular importance, and the direct can usually be limited to 1 to 2 hours or less. Also, every point raised in direct is potential material for cross-examination. Thus, unneeded complications or content are not neutral and primarily have a down side.

Visual displays can strengthen an expert's direct considerably by increasing interest and clarity. One might consider using at least one visual aid for each major point covered. It is usually preferable to keep demonstratives basic. A rule of thumb is to ask whether a visual aid is nearly, or completely, self-interpreting and can be comprehended quickly or with minimal explanation. Visual materials do not need to be fancy or elaborate, only clear. For example, a memory disorder in which rehearsal yields minimal gains in new learning can be easily illustrated through a learning curve. For visual displays, I often use overheads because the equipment is readily available, materials are inexpensive, materials can be blown up to sufficient size with little distortion, and one can keep the lights up in the room, a real advantage late in the day.

Some experts try to impress juries with their technical knowledge. In particular, their presentations are laden with jargon. Although some technical terms may be necessary and have exact meanings that are otherwise difficult to capture succinctly (e.g., "post-traumatic amnesia"), other terms are pedantic and contribute little. Overuse of jargon is likely to alienate jurors.

On direct and cross-examination, the expert should remember which audience is the important one. It is not either counsel, but the trier of fact—the judge or jury—that will make the ultimate decisions and that the expert is there to address. If the opposing attorney hates you, or acts like you are an object of disdain, it does not influence the outcome of the trial an iota if the jury feels otherwise. Answers often should be directed at the jury, that is, one should look at the jurors and speak to them.

Many points about cross-examination have already been covered, and only a few additions will be provided here. Cross-examination, as noted, often does not follow the outline of the direct examination, so that the expert should not be surprised if completely different topics are raised. Depositions may give helpful clues about at least some of the upcoming points of attack, but there will almost always be some unanticipated questions at trial. As with depositions, or more so, preparation is extremely important. In addition to a pre-trial meeting with the attorney, one should be familiar, or very familiar, with the file, and with key background literature.

It is exceptional to get through an entire cross-examination untouched, and few cases that get to trial are so one-sided that at least some reasonable counterarguments to the expert's opinions cannot be raised. In the end, if the expert has done a decent job on direct, and if the attorney scores some points on the cross-examination but misses as or more often, it is the cross-examiner who has probably lost considerable ground. One of the worst characteristics of some witnesses is to not concede anything, even the obvious, as if the loss of even one exchange is intolerable and completely nullifying. An expert who is defensive and unreasonable, and who does not make what would seem to be required concessions loses credibility. If the attorney asks, in the context of *DSM-IV* criteria for malingering, "Would you agree that lying on the interview could be viewed as lack of cooperation with the examination?" the simple answer would seem to be, "Yes." The attorney has not asked whether the expert thinks the plaintiff lied or whether the plaintiff was malingering. An expert might try to rush in to make these points, but a good attorney will simply say something like, "Doctor, I don't think you've answered my question. Please listen carefully," and then will slowly repeat the exact same question. If the expert again tries to dance around the question, she will begin to look evasive. When it seems to the jury that the expert would vehemently disagree should the cross-examiner assert that 1 + 1 = 2, he becomes an object of ridicule.

The expert's responsibility is to conduct herself competently, professionally, and ethically, not to win or lose the case, and not to influence the outcome through sleight of hand. If honest concessions lead the jury to reject the expert's opinion, so long as these concessions do not stem from avoidable error or negligence (e.g., scoring errors), it does not mean that the expert failed to perform in a respectable and worthy manner. It may well be that the jury reached the right decision and that justice has been done. The issues at stake in the courtroom are often of great personal import, and one hopefully would much prefer to have one's opinion rejected than to prevail if, in truth, one was wrong. Almost every attorney wins and loses cases, and a "bad" outcome will not necessarily lead them to develop negative views towards an expert. This is unlike a situation in which an expert has been dishonest with the attorney, by withholding weaknesses in his opinions, for example, and gets caught on the stand. Unfortunately, in some such instances, the expert's actions may have destroyed the chances that the meritorious party will prevail.

5.01.1 INTRODUCTION

Neither behavioral and emotional problems of children and adolescents, nor instances of positive functioning and healthy development that occur for these age groups, arise from biogenic, psychogenic, or sociogenic sources acting independently on the individual

(Lerner, 1986, 1995; Lerner, Hess, & Nitz, 1990, 1991). Rather, both problematic and healthy instances of behavior and development during childhood and adolescence—and indeed across the entire life-span—arise from the dynamic interaction (Lerner, 1978) or fusion (Tobach & Greenberg, 1984) of variables from multiple levels of organization. These levels include the biological (e.g., the genetic or hormonal), psychological (e.g., the cognitive or personological), social (e.g., peer group and family relational), and societal (e.g., educational, political, or economic institutional); and also involve the cultural, the designed and natural physical ecological, and the historical levels (Bronfenbrenner, 1979, in preparation; Elder, Modell, & Parke, 1993; Ford & Lerner, 1992; Lerner, 1986, 1991, 1995).

Thus, both the emergence of behavioral and emotional problems, and the risk for development of such problems, lies in the changing relations among multiple levels of organization that comprise the context, or the ecology, of human life (Bronfenbrenner & Morris, 1998; Lerner, 1995; Lerner et al., 1990). Similarly, development of positive, healthy behaviors (i.e., behaviors that meet, or fit, the behavioral, physical, or social demands of the context, and are thus able to be construed as "adaptive," or adjusted; Lerner & Lerner, 1983), and resistance to, or resiliency from, threats to development of such behaviors lie in integrations across time of biological-through-historical levels of organization, that is, in the micro and macro systems comprising the ecology of human behavior and development (Bronfenbrenner, 1979).

Accordingly, any attempts to describe or explain the problematic vs. healthy status of behavior, and/or the bases or actualization of risk or resiliency in human life, require reference to the relations between individuals and the contexts of human development. Simply, then, behavior or health problems, and risks and resiliency, require integrated consideration of people and the context within which they develop (Lerner, 1991, 1995, 1997; Sameroff, 1989). A "developmental contextual" (Lerner, 1986; Lerner & Kaufmann, 1985) theoretical frame is needed to understand, appraise, and devise policies and programs that promote positive human behavior and development (Lerner, 1995).

5.01.1.1 The Role of Developmental Contextual Theory

Developmental contextualism is a theory of human development that has direct importance for understanding the bases, assessment, and treatment of behavioral and emotional problems in childhood and adolescence (Lerner, 1986, 1995; Lerner et al., 1990, 1991). Behavioral/emotional problems involve the malfunctioning of the human psychosocial system (Magnusson & Öhman, 1987). Thus, development of behavioral/emotional problems involves the emergence of nonadaptive, nonfit, or inadequate characteristics in this psychosocial system. From a developmental contextual perspective, behavioral/emotional problems exist and develop when, and only when, an inadequate relation exists between psychological and social functioning, that is, between individuals and their context. It is a malfunctional person–context relation which defines problematic behavior and development; and it is from the changing nature of this relation—occurring normatively or through remedial, preventive, or enhancing interventions—that either healthy/positive or maladaptive, and hence negative, nonfit, or problematic behaviors develop (Sameroff, 1989).

We should emphasize that this relational, developmental contextual view is compatible with those of other developmentalists studying either clinical problems in childhood and adolescence and/or developmental psychopathology (e.g., Cicchetti, 1984, 1987; Magnusson, 1988; Magnusson & Öhman, 1987; Super, 1987; Wapner & Demick, 1988). To illustrate, Cicchetti (1987), writing about psychopathology during human infant development, notes that:

> it is inappropriate to focus on discrete symptomatology to infer the presence of nascent or incipient infant psychopathology. Rather, disorders in infancy are best conceptualized as relational psychopathologies, that is, as consequences of dysfunction in the parent–child–environment system. (p. 837)

A similar stress on the relational and developmental contextual character of psychopathology is made by Super (1987), who considers "disorders of development as a class of phenomena that reveal something of the nature of our children and also of the nature of the worlds we make for them" (p. 2). Indeed, he notes that:

> The settings, customs, and psychology of caretakers not only regulate the healthy emergence of human potential, they also shape the possibilities of disorder. At every stage of the etiology, expression, course, intervention, and final outcome of developmental problems, human culture structures the experience and adjusts the odds. (Super, 1987, p. 7)

In a corresponding vein, Öhman and Magnusson (1987) indicate that:

> any disease must be understood as resulting from a multiplicity of causal events spanning observational levels from biochemistry to sociology. Thus, any single-factor, linear causal model is unrealistic for understanding disease in general, and mental disorders in particular. Instead, multiple interacting causal factors that often change in their effect over time must be postulated. (p. 18)

(see also Magnusson, 1988; Magnusson & Allen, 1983; Super & Harkness, 1982, 1986).

Given, then, the apparent prominence of ideas pertinent to a developmental contextual perspective for understanding development across the life-span and, for present purposes, the pertinence of this perspective for conceptualizing the developmental, contextual, and individual-ecological relational bases of child and adolescent problem behaviors, or resiliency to the emergence of such problems, it is useful to discuss the features of developmental contextualism.

5.01.2 AN OVERVIEW OF DEVELOPMENTAL CONTEXTUALISM

Children and adolescents, and their families, communities, and societies develop; they show systematic and successive changes over time (Lerner, 1986). These changes are interdependent. Changes within one level of organization, for example, developmental changes in personality or cognition within the individual, are reciprocally related to developmental changes within other levels, such as those involving changes in caregiving patterns or spousal relationships within the familial level of organization (e.g., Hetherington, Lerner, & Perlmutter, 1988; Lerner, 1984; Lerner & Spanier, 1978; Lewis, 1997; Lewis & Rosenblum, 1974).

Moreover, reciprocal changes among levels of organization are both products and producers of reciprocal changes within levels. For example, over time, parents' "styles" of behavior and of rearing influence children's personality and cognitive functioning and development; in turn, interactions between personality and cognition constitute an emergent "characteristic" of human individuality that affects parental behaviors and styles and the quality of family life (e.g., Baumrind, 1995; Lerner, 1978, 1982; Lerner & Busch-Rossnagel, 1981; Lerner, Castellino, Terry, Villarruel, & McKinney, 1995; Lewis, 1997; Lewis & Rosenblum, 1974).

Within developmental contextualism, levels are conceived of as integrative organizations. That is:

> the concept of integrative levels recognizes as equally essential for the purpose of scientific analysis both the isolation of parts of a whole and their integration into the structure of the whole. It neither reduces phenomena of a higher level to those of a lower one, as in mechanism, or describes the higher level in vague nonmaterial terms which are but substitutes for understanding, as in vitalism. Unlike other "holistic" theories, it never leaves the firm ground of material reality ... The concept points to the need to study the organizational interrelationships of parts and whole. (Novikoff, 1945, p. 209)

Moreover, Tobach and Greenberg (1984) have stressed that:

> the interdependence among levels is of great significance. The dialectic nature of the relationship among levels is one in which lower levels are subsumed in higher levels so that any particular level is an integration of preceding levels ... In the process of integration, or fusion, *new* levels with their own characteristics result. (p. 2)

The course of human development is the product of the processes involved in the "dynamic interactions" (Lerner, 1978, 1979, 1984) among integrative levels.

In emphasizing that systematic and successive change (i.e., development) is associated with alterations in the dynamic relations among structures from multiple levels of organization, developmental contextualism provides a scope for contemporary developmental research and intervention that is not limited by (or, perhaps better, confounded by an inextricable association with) a unidimensional portrayal of the developing person (e.g., the person seen from the vantage point of only cognitions, or emotions, or stimulus–response connections, or genetic imperatives; e.g., see Piaget, 1970; Freud, 1949; Bijou & Baer, 1961; and Rowe, 1994, respectively). Rather, the power of the stress in developmental contextualism on processes of dynamic person–context relations is the "design criteria" imposed on research, method, and intervention pertinent to the study of any content area or dimension of the developing person. This power is constituted by four interrelated assumptive dimensions of developmental contextual theory (Lerner, 1998). Accordingly, it is useful to discuss these dimensions in order to illuminate the key theoretical and methodological (e.g., research design and measurement) issues pertinent to understanding how biological, psychological, and contextual processes combine to promote either healthy or problematic behavior and development across the life-span and also within the periods of childhood and adolescence.

5.01.2.1 Change and Relative Plasticity

The central idea in developmental contextualism is that changing, reciprocal relations (or dynamic interactions) between individuals and the multiple contexts within which they live comprise the essential process of human development (Lerner, 1986; Lerner & Kauffman, 1985). Accordingly, developmental contextualism stresses that the focus of developmental understanding must be on systematic change (Ford & Lerner, 1992). This focus is required because of the belief that the potential for change exists across the life-span (e.g., Baltes, 1987). Although it is also assumed that systemic change is not limitless (e.g., it is constrained by both past developments and by contemporary contextual conditions), developmental contextualism stresses that relative plasticity exists across life (Lerner, 1984). The resilient behavior in children and adolescents provides a concrete instance of such plasticity (Masten, 1989; Werner, 1990, 1995).

There are important implications of relative plasticity for the application of development science to address problems of human behavior and development. For instance, the presence of relative plasticity legitimates a proactive search across the life-span for characteristics of people and of their contexts that, together, can influence the design of policies and programs promoting positive development (Birkel, Lerner, & Smyer, 1989; Fisher & Lerner, 1994; Lerner & Hood 1986).

5.01.2.2 Relationism and the Integration of Levels of Organization

From a developmental contextual perspective, human behavior is both biological and social (Featherman & Lerner, 1985; Tobach & Schneirla, 1968). In fact, no form of life as we know it comes into existence independent of other life. No animal lives in total isolation from others of its species across its entire life-span (Tobach, 1981; Tobach & Schneirla, 1968). Biological survival requires meeting demands of the environment or, as we note later, attaining a goodness of fit (Chess & Thomas, 1984; Lerner & Lerner, 1983, 1989; Thomas & Chess, 1977) with the context. Because this environment is populated by other members of one's species, adjustment to (or fit with) these other organisms is a requirement of survival (Tobach & Schneirla, 1968).

Developmental contextualism emphasizes that the bases for change, and for both plasticity and constraints in development, lie in relations that exist among multiple levels of organization that comprise the substance of human life (Ford & Lerner, 1992; Schneirla, 1957; Tobach, 1981). These levels range from the inner biological level, through the individual/psychological level and the proximal social relational level (e.g., involving dyads, peer groups, and nuclear families), to the sociocultural level (including key macro-institutions such as educational, public policy, governmental, and economic systems) and the natural and designed physical ecologies of human development (Bronfenbrenner, 1979; Riegel, 1975). These levels are structurally and functionally integrated, thus requiring a systems view of the levels involved in human development (Ford & Lerner, 1992; Sameroff, 1983; Smith & Thelen, 1993; Thelen & Smith, 1994).

Developmental contextualism (Lerner, 1986, 1991, 1995) is one instance of such a developmental systems perspective and, as such, promotes a relational unit as a requisite for developmental analysis (Lerner, 1991): variables associated with any level of organization exist (are structured) in relation to variables from other levels; qualitative and quantitative dimensions of the function of any variable are also shaped by the relations that the variable has with variables from other levels. Unilevel units of analysis (or components of, or elements in, a relation) are not an adequate target of developmental analysis; rather, the relation itself—the interlevel linkage—should be the focus of such analysis (Lerner, 1991; Riegel, 1975).

Relationism and integration have a clear implication for unilevel theories of development and for approaches to intervention that emphasize a similarly unilevel (e.g., a psychogenic or biogenic) orientation to etiology or "treatment": at best, such approaches are severely limited, and inevitably provide a nonveridical depiction of development, due to their focus on what are essentially main effects embedded in higher order interactions (e.g., see Walsten, 1990); at worst, such approaches are neither valid nor useful. Accordingly, neither biogenic theories or interventions (e.g., ones based on genetic reductionistic conceptions such as behavioral genetics or sociobiology; Freedman, 1979; Plomin, 1986; Rowe, 1994; Wilson, 1975), psychogenic theories or interventions (e.g., behavioristic or functional analysis models; Baer, 1970, 1976; Bijou, 1976; Bijou & Baer, 1961; Skinner, 1938), nor sociogenic theories or interventions (e.g., "social mold" conceptions of socialization; e.g., Homans, 1961; and see Hartup, 1978, for a review) provide adequate frames for understanding or addressing problems of human development. Interventions based on such theories are insufficiently attentive to the potential plasticity that exists in the human development system, and thus the multiple levels of this system that provide "points of entry" for useful interventions (Birkel, Lerner, & Smyer, 1989; Lerner, 1984, 1995).

Developmental contextualism moves beyond simplistic division of sources of development into nature-related and nurture-related variables or processes. Instead, developmental contextualism sees multiple levels of organization that exist within the ecology of human development as part of an inextricably fused developmental system, one that affords formulation of a rich and multilevel array of strategies for developmental interventions into the life course (for example, see the chapters in Lerner, 1998).

5.01.2.3 Historical Embeddedness and Temporality

The relational units of analysis of concern in developmental contextualism are considered "change units" (Lerner, 1991). The change component of these units derives from the ideas that all levels of organization involved in human development are embedded in history, that is, they are integrated with historical change (Elder, 1980; Elder et al., 1993). Relationism and integration mean that no level of organization functions as a consequence of its own, isolated activity (Tobach, 1981; Tobach & Schneirla, 1968). Each level functions as a consequence of its structural integration with other levels (Tobach & Greenberg, 1984). History—change over time—is incessant and continuous, and it is a level of organization that is fused with all other levels. This linkage means that change is a necessary, an inevitable, feature of variables from all levels of organization (Baltes, 1987; Lerner, 1984); in addition, this linkage means that the structure, as well as the function, of variables changes over time.

The continuity of change that constitutes history can lead to both intra-individual (or, more generally, intralevel) continuity or discontinuity in development, depending on the rate, scope, and particular substantive component of the developmental system at which change is measured (Brim & Kagan, 1980; Lerner, 1986, 1988; Lerner & Tubman, 1989). Thus, continuity at one level of analysis may be coupled with discontinuity at another level; quantitative continuity or discontinuity may be coupled with qualitative continuity or discontinuity within and across levels; and continuity or discontinuity can exist in regard to both the processes involved in (or "explanations" of) developmental change and in the features, depictions, or outcomes (i.e., the "descriptions") of these processes (Cairns & Hood, 1983; Lerner, 1986).

These patterns of within-person change pertinent to continuity and discontinuity can result in either constancy or variation in rates at which different individuals develop in regard to a particular substantive domain of development. Thus, any pattern of intra-individual change can be combined with any instance of interindividual differences in within-person change, that is, with any pattern of stability or instability (Lerner, 1986; Lerner & Tubman, 1989). In other words, continuity–discontinuity is a dimension of intra-individual change and is distinct from, and independent of, stability–instability, which involves between-person change, and is, therefore, a group, and not an individual, concept (Baltes & Nesselroade, 1973; Lerner, 1976, 1986).

In sum, since historical change is continuous, temporality is infused in all levels of organization. This infusion may be associated with different patterns of continuity and discontinuity across people. The potential array of such patterns has implications for understanding the importance of human diversity, and design and implementation of interventions into the course of human development.

5.01.2.4 The Limits of Generalizability, Diversity, and Individual Differences

The temporality of the changing relations among levels of organization means that changes that are seen within one historical period (or time of measurement), and/or with one set of instances of variables from the multiple levels of the ecology of human development, may not be seen at other points in time (Baltes, Reese, & Nesselroade, 1977; Bronfenbrenner, 1979; Valsiner, 1998). What is seen in one data set may be only an instance of what does or what could exist. Accordingly, developmental contextualism focuses on diversity: of people, of relations, of settings, and of times of measurement (Lerner, 1991, 1995, 1997).

Individual differences within and across all levels of organization are seen as having core, substantive significance in understanding human development (Baltes et al., 1977; Lerner, 1991, 1995, 1997) and for designing interventions that fit specific needs and characteristics of diverse groups toward which such efforts may be directed. Indeed, diversity is the exemplary illustration of the presence of relative plasticity in human development (Lerner, 1984). Moreover, by inferring that it is possible to generalize from across-person variation that exists within time to within-person variation across time, diversity constitutes the best evidence of the potential for change in the states and conditions of human life (Brim & Kagan, 1980). It underscores the belief that interventions can make a difference in human development.

Moreover, individual structural and functional characteristics constitute an important source of people's development (Lerner, 1982; Lerner & Busch-Rossnagel, 1981). The individuality of each person promotes variation in the fusions he or she has with the levels of organization within which the person is embedded. For instance, people's distinct actions or physical features promote differential actions (or reactions) in others toward them (Lerner, 1987). These differential actions, which constitute feedback to the person, shape, at least in part, further change in the person's characteristics of individuality (Lerner & Lerner, 1989; Schneirla, 1957). For example, the changing match, congruence, or goodness of fit between people's developmental characteristics and their context provide a basis for consonance or dissonance in their ecological milieu; the dynamic nature of this interaction constitutes a source of variation in positive and negative outcomes of developmental change (Lerner et al., 1990, 1991; Lerner & Lerner, 1983; Thomas & Chess, 1977; Thomas, Chess, Birch, Hertzig & Korn, 1963).

The major assumptive dimensions of developmental contextualism—systematic change and relative plasticity, relationism and integration, embeddedness and temporality, generalizability limits and diversity—are very much intertwined facets of a common conceptual core. And, as is also the case with levels of organization that are integrated to form the substance of developmental change, the assumptive dimensions reflect the essential features of superordinate developmental systems views of human development (Ford & Lerner, 1992). As is the case with the several defining features of the life-span developmental perspective, which—according to Baltes (1987)—need to be considered as an integrated whole, the assumptive dimensions of developmental contextualism need to be appreciated simultaneously. Such appreciation is required to understand the breadth, scope, and implications for research and application of this conceptual framework.

5.01.3 BASES AND IMPLICATIONS OF DEVELOPMENTAL CONTEXTUALISM AND CHILD AND ADOLESCENT DEVELOPMENT

Since the early 1970s the study of children and their contexts has evolved in at least three significant directions: changes in the conceptualization of the nature of the person; the emergence of a life-span perspective about human development; and stress on the contexts of development. These trends were both products and producers of developmental contextualism. This perspective has promoted a rationale for a synthesis of research and outreach; a synthesis focused on the diversity of children and on the contexts within which they develop.

Much of the history of the study of human development prior to the mid-1970s was predicated on either organismic or mechanistic (reductionistic) models (Overton & Reese, 1973, 1981; Reese & Overton, 1970). In turn, it is accurate to say that since the 1970s, developmental contextual conceptions have been increasingly prominent bases of scholarly advances in human development theory and methodology (Dixon & Lerner, 1992; Dixon, Lerner, & Hultsch 1991; Lerner, Hultsch, & Dixon, 1983; Riegel, 1975, 1976a, 1976b; Sameroff, 1975, 1983). Indeed, the three above-noted themes in the study of human development define the place of developmental contextualism in theory and research since the late 1970s. Accordingly, it is useful to discuss each of these themes in some detail.

5.01.3.1 Children's Influences on Their Own Development

Children have come to be understood as active producers of their own development (Bell, 1968; Lerner & Spanier, 1978; Lewis & Rosenblum, 1974; Thomas et al., 1963). These contributions primarily occur through the reciprocal relations individuals have with other significant people in their context: for example, children with family members, caregivers, teachers, and peers.

The content and functional significance of the influences that people have on others and, in turn, on themselves, occur in relation to people's characteristics of individuality (Schneirla, 1957). Individual differences in people evoke differential reactions in others, reactions which provide feedback to people and influence the individual character of their further development (Schneirla, 1957). Accordingly, individuality—diversity among people—is central in understanding the way in which any given person is an active agent in his or her own development (Lerner, 1982, 1991; Lerner & Busch-Rossnagel, 1981). Thus, as we have emphasized, diversity has core, substantive meaning and, as such, implications for all studies of human development.

To illustrate these points, it is useful to recall the old adage "the child is father of the man." This means simply that people's characteristics when they are children relate to their characteristics during adulthood. However, there is another way of interpreting this quotation: How we behave and think as adults—and perhaps especially as parents—is very much influenced by our experiences with our children. Our children rear us as much as we do them. Because we are parents, we are different adults than we would be if we were childless. But, more importantly, the specific and often special characteristics of a particular child influence us in unique ways. How we behave toward our children depends to a significant extent on how they have influenced us to behave. Such child influences are termed "child effects."

The presence of such child effects constitutes the basis of bidirectional relations between parents and children. This bidirectional relation continues when the child is an adolescent and an adult. Corresponding relations exist between people and siblings, friends, teachers, and indeed all other significant people in their life. Indeed, this child–other relation is the basic feature of the developmental contextual relations that characterize the social creature we call a human being.

Child effects emerge largely as a consequence of a child's individual distinctiveness. All children, with the exception of genetically identical (monozygotic) twins, have a unique genotype, that is, a unique genetic inheritance. Similarly, no two children, including monozygotic twins, experience precisely the same environment. All human characteristics, be they behavioral or physical, arise from an interrelation of genes and environment (Anastasi, 1958; Lerner, 1986). Given the uniqueness of each child's genetic inheritance and environment, the distinctiveness of each child is assured (Hirsch, 1970; Feldman & Lewontin, 1975). In other words, every child is unique and therefore individually different from every other child.

This individuality may be illustrated by drawing on the study of temperament (Chess & Thomas, 1984; Thomas & Chess, 1977; Thomas et al., 1963). Temperament is a characteristic of children's behavior that describes how they act. For instance, all children eat and sleep. Temperament is the style of eating or sleeping shown by the child; if the child eats the same amount at every meal and/or gets hungry at the same time, then this child has, in regard to eating, a regular, or rhythmic, temperament. A child who gets hungry at different times of the day, or who may eat a lot or a little without any seeming predictability, would, in regard to eating, have an arrhythmic temperament. Similarly, obviously all children sleep. However, some children may sleep irregularly, that is, for seemingly unpredictable (at least to their parents) lengths of time, periods interspersed with wakeful periods of crying and fussing. Simply, one child may be an arrhythmic eater and sleeper, whereas another child might sleep and eat in a more regularly patterned way, and/or when awake may show more smiling than crying and fussing.

The importance of these individual differences arises when we recognize that, as a consequence of their individuality, children will present different stimulation to parents. Children with the above-noted temperamental styles present different stimuli to their parents as a consequence of their respective eating and sleep/wake patterns; the experience for a parent of having a pleasant, regularly sleeping child, who is predictable in regard to eating habits as well, is quite different from the experience for a parent who has a moody, irregularly sleeping and eating child. However, the effect of the child's stimulation of the parent depends in part on the parent's own characteristics of individuality. To explain this point it is useful to consider the second theme in the literature that helped crystallize the developmental contextual view of human development.

5.01.3.2 Development as a Life-span Phenomenon

The emergence of interest during the 1970s and 1980s in a life-span perspective about human development led to the understanding that development occurs in more than the childhood or adolescent years (Baltes, 1968, 1987; Block, 1971; Brim & Kagan, 1980; Elder, 1974, 1980; Featherman, 1983; Riley, 1979; Schaie, 1965). Parents as well as children develop as distinct individuals across life (Lerner & Spanier, 1978). Parents develop both as adults in general and, more specifically, in their familial and extrafamilial (for example, vocational or career) roles (Vondracek, Lerner, & Schulenberg, 1986). Indeed, the influence of children on their parents will depend in part on the prior experience the adult has had with the parental role and on the other roles in which the parent is engaged (e.g., worker, adult–child, and caregiver for an aged parent) (Hetherington &

Baltes, 1988). Thus, people's unique history of experiences and roles, as well as their unique biological (e.g., genetic) characteristics, combine to make them unique, and with time, given the accumulation of the influences of distinct roles and experiences, increasingly more so across the course of life (Lerner, 1988). This uniqueness is the basis of the specific feedback parents give to their individual children.

That is, parents who are stimulated differentially may be expected to differentially react to, or process (e.g., think and feel about) the stimulation provided by their child. A child with an irregular temperament might evoke feelings of frustration and exasperation and thoughts of concern in his or her parents (Brazelton, Koslowski, & Main, 1974; Lewis & Rosenblum, 1974). We might expect, however, that the parents of a child with a predictable and rhythmic style would be better rested than would the parents of an arrhythmic child. When the rhythmic child was awake, they would have a child with a more regularly positive mood, and this too would present less stress on them as parents and as spouses.

The individuality of parental reactions underscores the idea that parents are as individually distinct as their children. Not all parents of an irregularly eating and sleeping, moody child will react with concern and/or frustration. Similarly, some parents will be stressed by even the most regular, predictable, and positive of children. Such parental individuality makes child effects more complicated to study. However, at the same time, parental individuality underscores the uniqueness of each child's context. Simply, then, it may be expected that, as a consequence of the different stimulation received from their children, and in relation to their own characteristics of individuality, parents will provide differential feedback to their children.

Such differential feedback may take the form of different behavior shown to children by parents and/or of different emotional climates created in the home (Brazelton et al., 1974). For instance, parents of an irregular child might take steps to alter his or her eating and sleep/wake patterns. In regard to sleeping, they might try to cut naps short during the day in order that the child be more tired in the evening. In addition, during the time when they are appraising the success of their attempts to put the child on an imposed schedule a general sense of tenseness might pervade the household. "Will we have another sleepless night? Will we be too tired to be fully effective at work?" they might wonder.

The presence of differential feedback by parents of temperamentally distinct children becomes an important part of the child's experience, and this feedback is distinct in that it is based on the effect of the child's individuality on the parent. Thus, the feedback serves to promote the child's individuality further.

5.01.3.2.1 Circular functions and bidirectional socialization

The reciprocal child–parent relations involved in child effects constitute a circular function (Schneirla, 1957) in individual development: children stimulate differential reactions in their parents, and these reactions provide the basis of feedback to the children, that is, return stimulation which influences their further individual development. These circular functions underscore the point that children (and adolescents, and adults) are producers of their own development and that people's relations to their contexts involve bidirectional exchanges (Lerner, 1982; Lerner & Busch-Rossnagel, 1981). Parents shape their children, but part of what determines the way in which they do this is the children themselves.

Children shape their parents—as adults, as spouses, and of course as parents *per se*—and in so doing, children help organize feedback to themselves, feedback which contributes further to their individuality and thus the circular function starts all over again (that is, the child effects process returns to its first component). Characteristics of behavioral or personality individuality allow the child to contribute to this circular function. However, this idea of circular functions needs to be extended; that is, in and of itself the notion is silent regarding specific characteristics of the feedback (e.g., its positive or negative valence) children will receive as a consequence of their individuality. In other words, to account for the specific character of child–context relations the circular functions model needs to be supplemented; this is the contribution of the goodness-of-fit model.

5.01.3.2.2 The goodness-of-fit model

Just as children bring their characteristics of individuality to a particular social setting there are demands placed on them by virtue of the social and physical components of the setting. These demands may take the form of: (i) attitudes, values, or stereotypes that are held by others in the context regarding the person's attributes (either physical or behavioral characteristics); (ii) the attributes (usually behavioral) of others in the context with whom the child must coordinate, or fit, his or her attributes (also, in this case, usually behavioral) for adaptive interactions to exist; or, (iii) the physical characteristics of a setting (e.g., the presence or absence of access ramps for the motorically handicapped) which require the child to possess certain attributes (again, usually behavioral abilities) for the most efficient interaction within the setting to occur.

Children's individuality, in differentially meeting these demands, provides a basis for the specific feedback they get from the socializing environment. For example, considering the demand "domain" of attitudes, values, or stereotypes, teachers and parents may have relatively individual and distinct expectations about behaviors desired of their students and children, respectively. Teachers may want students who show little distractibility, but parents might desire their children to be moderately distractible, for example, when they require their children to move from television watching to dinner or to bed. Children whose behavioral individuality was either generally distractible or generally not distractible would thus differentially meet the demands of these two contexts. Problems of adjustment to school or to home might thus develop as a consequence of a child's lack of match (or goodness of fit) in either or both settings. In turn, interventions aimed at ameliorating or preventing such problems should focus on enhancing fit—on improving the child–context relation—and not on either child or context alone.

The importance of such an approach to intervention is underscored by the research of Thomas and Chess (1977, 1980, 1981) and Lerner and Lerner (1983, 1989). These researchers have found that if a child's characteristics of individuality provide a goodness of fit with demands of a particular setting, adaptive outcomes will accrue in that setting. Those children whose characteristics match most of the settings within which they exist receive supportive or positive feedback from the contexts and show evidence of the most adaptive behavioral development. In turn, of course, poorly fit, or mismatched, children—those whose characteristics are incongruent with one or most settings—appear to show alternative developmental outcomes.

In sum, then, the literature on child effects and on the life-span perspective promote a concern with individual differences; with variation in developmental pathways across life; and with the developmental contextual idea that changing relations (occurring "naturally" or through interventions) between people and their context provide the basis, across life, of the individual's unique repertoire of physical, psychological, and behavioral characteristics (Lerner, 1991). The recognition of this link between person and context was a product and a producer of the third theme emerging in the study of human development since the 1970s.

5.01.3.3 Development in its Ecological Context

The study of children and their parents became increasingly "contextualized," or placed within the broader "ecology of human development," during this period (Bronfenbrenner, 1977, 1979; Elder, 1974; Garbarino, 1992; Pepper, 1942). This focus has involved a concern with the "real life" situations within which children and families exist; it has also led to the study of the bidirectional relations between the family and other social settings within which children and parents function, for instance, the workplace, the welfare office, the day-care center, the Medicaid screening office, and the formal and the nonformal educational and recreational settings present in a neighborhood or a community (Lewis & Feiring, 1978; Lewis & Rosenblum, 1974). Thus, fit between youth and their contexts involves much more than relations between children and their parents and, as we have emphasized, interventions to enhance the congruence between person and context can involve any one or several levels within the ecology of human development.

To understand how the social context contributes to bidirectional person–context relations, we should reiterate that a child is not best thought of as merely similar to all other children, or as simply different from others with respect to only one, or even just a few, characteristics. Instead, individual differences exist with respect to numerous characteristics. We have illustrated how at least some of these changes occur through bidirectional relations children have with their parents. However, we have not yet stressed that parents too are made up of multiple dimensions of individuality which, as with the child, develop across time (e.g., see Baltes, 1987).

Another point not yet illustrated is that both the child and the parent have other social roles. These roles lead both children and parents into social relationships with other groups of people, that is, with other social networks. Parents are also spouses, adult children of their own parents, workers, and neighbors. Children also may be siblings and friends of other children; and as they progress through childhood and, later, adolescence, they become students and often at least part-time employees, respectively. The sorts of relationships in these other social networks in which children and parents engage when outside of their role of child or parent, respectively, can be expected to influence the parent–child relationship (Bronfenbrenner, 1977, 1979).

A child's poor performance at school may influence his or her behavior in the home, and especially, may alter the quality of the parent–

child relationship. In turn, a problematic home situation—as is experienced by children in families wherein parental abuse or neglect of the child occurs—will affect the child's relationships with peers, teachers, and other family members (Baca Zinn & Eitzen, 1993; Belsky, Lerner, & Spanier, 1984).

In regard to parents, strain in the spousal relationship can occur if adults spend too much energy in their parental caregiving role (J. V. Lerner, 1994). For instance, a child's unpredictable sleep pattern and negative mood when awake can severely tax a parents' energy. Energy and time needed for parents to be good spouses to each other therefore may not be available. In addition, the fatigue caused by the demands of parental roles can be expected to influence parents' performance in the workplace (J. V. Lerner, 1994). It is difficult for people who have been up all night caring for a crying infant to be at their best at work the next morning. In turn, of course, problems at work can be brought home. Parents whose energies are significantly depleted outside the home may not have the stamina during the evening to be attentive, patient parents to their children (or attentive, emotionally supportive spouses for their mates).

Thus, bidirectional relationships exist between child and parent (Bornstein & Tamis-LeMonda, 1990; Lerner & Lerner, 1987); and these relationships are in turn reciprocally related to other social networks within which the dyad exists and to the broader societal and cultural context. For example, studying mother–infant dyads in the United States, France, and Japan, Bornstein et al. (1992) found both culture-general and culture-specific patterns of maternal responsiveness to characteristics of infant individuality (e.g., in regard to activity level, exploration, and vocalization). In short, relationships among children, parents, and contexts constitute a complex state of affairs.

One approach to the conceptualization of these relations that we see as particularly useful has been proposed by Bronfenbrenner and his colleagues (e.g., Bronfenbrenner & Crouter, 1983; Bronfenbrenner & Morris, 1998; Garbarino, 1992). Bronfenbrenner's work has been a major catalyst in promoting the contextualization of human development, and in helping us understand why the study of development must move beyond its status during the 1970s, as "the science of the strange behavior of children in strange situations with strange adults for the briefest possible periods of time" (Bronfenbrenner, 1977, p. 513). Bronfenbrenner (1977, 1979, 1983) has argued that human development needs to be understood as it occurs in its real-world setting or "ecology." He believes that this ecology of human development is composed of four distinct although interrelated systems, or types of settings.

The first, the "microsystem" is composed of "the complex of relations between the developing person and environment in an immediate setting containing the person" (Bronfenbrenner, 1977, p. 515). Furthermore, an infant's microsystems may be interrelated. What occurs in day care may affect what happens in the family, and vice versa. The second ecological stratum, termed the "mesosystem," is defined as "the interrelations among major settings containing the developing person at a particular point in his or her life" (e.g., the interaction between day care and family: Bronfenbrenner, 1977, p. 515).

Bronfenbrenner labels the third system as the "exosystem" and defines it as:

> an extension of the mesosystem embracing . . . specific social structures, both formal and informal, that do not themselves contain the developing person but impinge upon or encompass the immediate setting in which the person is found, and thereby delimit, influence, or even determine what goes on there [e.g., the parent's social role as "worker"]. (Bronfenbrenner, 1977, p. 515)

Finally, Bronfenbrenner notes that there exists a "macrosystem" within the ecology of human development. This system is composed of cultural values and beliefs as well as historical events (e.g., wars, floods, famines), both of which may affect other ecological systems.

In short, then, Bronfenbrenner's model of the ecology of human development allows us to devise a means to represent the idea that the bidirectional socialization which occurs between children and parents is embedded in a still more complex system of social networks and of societal, cultural, and historical influences. This system represents a rich set of "targets of opportunity" for the design, delivery, and sustainability of interventions into the course of human development.

5.01.3.3.1 Levels of embeddedness in the ecology of human development

The core idea in developmental contextualism is that the organism (organismic attributes or, most generally, biology) and context cannot be separated (Gottlieb, 1991, 1992; Lerner, 1984; Tobach, 1981). Both are fused across all of life, and thus across history. One way to illustrate just what is involved in this relation, even for one person, is to consider the diagram presented in Figure 1 (see Lerner, 1984, 1986).

It is important to indicate at this point that we may speak of dynamic interactions between

parent and child that pertain to either social or physical (for instance, biological or physiological) relations. For example, in regard to social relationships, the parent "demands" attention from the child, but the child does not show it; this "lights" the parent's "short fuse" of tolerance; the parent scolds the child, who then cries; this creates remorse in the parent and elicits soothing behaviors from him or her; the child is calmed, snuggles up to the parent, and now both parties in the relationship show positive emotions and are happy (see Tubman & Lerner, 1994, for data pertinent to such parent–child relationships).

In turn, we may also illustrate dynamic interactions which involve not only the exchange of "external" social behaviors but also involve biological or physiological processes. For example, parental religious practices, rearing practices, or financial status may influence the child's diet and nutritional status, health, and medical care. In turn, the contraction of an infectious disease by either parent or child can lead to the other member of the relationship contracting the disease. Moreover, the health and physical status of the child influences the parents' own feelings of well-being and thus hopes and aspirations regarding the child (Finkelstein, 1993).

Thus, Figure 1 illustrates that within and among each of the networks which is depicted, one may conceive of bidirectional relationships existing among the people populating the network. A child effect may function, in a sense, like a small pebble thrown into a quiet lake. It can prompt a large ripple. In turn, of course, the reverse of this possibility can occur. Events in settings lying far beyond the child–parent relationship can influence it. For instance, the resources in a community for child day care during the parent's working hours, the laws (e.g., regarding tax exemptions) or social programs available in a society supporting day care, and the cultural values regarding families who place their infants in day care, all exert an impact on the quality of the parent–child relationship.

Moreover, as we have just noted, the child–parent relationship, and the social networks in which it is located, are embedded in still larger community, societal, cultural, and historical levels of organization. These relations are illustrated also in Figure 1. Time (history) cuts through all the systems. This feature of the figure is introduced to remind us that, as with the people populating these social systems, change is always occurring. Diversity within time is created as change across time introduces variation into all levels of organization involved in the system depicted in Figure 1.

In other words, all changes are embedded in history (Baltes, 1987; Elder, 1974; Elder et al., 1993), that is, time "cuts through" all levels of organization. As such, the nature of parent–child relations, of family life and development, and of societal and cultural influences on the child–parent–family system are influenced by both normative and non-normative historical changes (Baltes, 1987) or, in other words, by "evolutionary" (i.e., gradual) and "revolutionary" (i.e., abrupt; Werner, 1957) historical changes. This system of multiple, interconnected, or "fused" (Tobach & Greenberg, 1984) levels comprises a complete depiction of the integrated organization involved in the developmental contextual view of human development (Lerner, 1986, 1991).

5.01.4 IMPLICATIONS FOR METHOD AND APPLICATION

In essence, (i) individuality (diversity); (ii) change, involving both the individual and the context; and, as a consequence; (iii) further individuality, are the essential features of human development within developmental contextualism. Given that the multiple levels of change involved in person–context relations may involve individuals at any point in their lives—whether they are infants or young children, on the one hand, or adults (and acting in roles such as parents, spouses, or teachers), on the other—it is possible to see why a developmental contextual perspective provides a useful frame for studying development across the life-span and a rich opportunity to design and implement both individual and group interventions into the course of human life.

The possibility that bidirectional relations exist across the life-span among all the levels shown in Figure 1 represents a formidable state of complexity, but one which behavioral and social science theory, research, and intervention must address. If the scholarship of research and application does not cope with this complexity, then neither research nor intervention will be adequate. That is, research inattentive to the complexity of person–context relations will be deficient in that either it will fail to appreciate the substantive nature of individual, familial, or relationship variation and/or it will mistakenly construe variation around some mean level as, at best, error variance (Lerner, 1991, 1997). In turn, applications—policies and/or intervention programs (that are at least ideally) derived from research (Lerner & Miller, 1993)—will insufficiently fit with the needs of the specific people intended to be served by these interventions, if it is the case that these activities are insufficiently informed by knowledge about the specific characteristics of individuality of these groups. However, developmental contextualism offers an alternative to this situation. It does so by stressing the importance of a focus on diversity and context for integrated research and application.

As we have emphasized, developmental contextualism stresses the bidirectional connections between individuals and the actual ("ecologically valid") settings within which they live. This emphasis has brought to the fore of concern in the social and behavioral sciences both "diversity" (individual differences) and "context" (of peoples and their sociocultural institutions). In addition, we have explained that developmental contextualism emphasizes the relation between individuals and their context, a focus that has resulted in the recognition that a synthesis of perspectives from multiple disciplines is needed to understand the multilevel (e.g., person, family, and community) integrations involved in human development. Furthermore, there has been a recognition that to understand the basic process of human development—the process involved in the changing relations between individuals and contexts—both descriptive and explanatory research must be conducted within the actual ecology of people's lives.

Descriptive research involves the depiction, or representation, of development as it exists for a given person or group, in one or more contexts, at one or more points in time. Explanatory research involves the introduction (through manipulation or statistical modeling) of variation into such person–context relations. These planned variations in the course of human life are predicated on: (i) theoretical ideas about the source of particular developmental phenomena (for specific combinations of people and contexts); or on (ii) theoretically guided interests about the extent to which a particular developmental phenomenon (e.g., cognitive development in the aged years) may show systematic change in structure and/or function, that is plasticity, across the life-span (Baltes, 1987; Lerner, 1984). In either of the above cases such researcher-introduced variation is an attempt to simulate the "natural" variation of life; if theoretical expectations are confirmed, the outcomes of such investigations provide an explanation of how developmental change occurs within a person or group.

Given the developmental contextual focus on studying person–context relations within the actual ecology of human development, explanatory investigations by their very nature constitute intervention research. In other words, the goal of developmental contextual explanatory research is to understand the ways in which variations in ecologically valid person–context relations account for the character of actual or potential trajectories of human development, that is, life paths enacted in the "natural laboratory" of the "real world." Therefore, to gain understanding of how theoretically relevant variations in such person–context relations may influence actual or to-be-actualized developmental trajectories, the researcher may introduce policies and/or programs as, if you will, "experimental manipulations" of the proximal and/or distal natural ecology. Evaluations of outcomes of such interventions become, then, a means to bring data to bear on theoretical issues pertinent to changing person–context relations and, more specifically, to the plasticity in human development that may exist, or that may be capitalized on, to enhance human life (Lerner, 1988). In other words, a key theoretical issue for explanatory research in human development is the extent to which changes—in the multiple, fused levels of organization comprising human life—can alter the structure and/or function of behavior and development.

Of course, independent of any researcher-imposed attempts to intervene in the course of human development, the naturally occurring events experienced by people constantly shape, texture, and help direct the course of their lives. That is, the accumulation of the specific roles and events a person experiences across life—involving normative age-graded events, normative history-graded events, and non-normative events (Baltes, 1987; Baltes, Reese, & Lipsitt, 1980)—alters each person's developmental trajectory in a manner that would not have occurred had another set of roles and events been experienced. The between-person differences in within-person change that exist as a consequence of these naturally occurring experiences attest to the magnitude of the systematic changes in structure and function—the plasticity—that characterizes human life (Lerner, 1984).

Explanatory research is necessary, however, to understand what variables, from what levels of organization, are involved in particular instances of plasticity that have been seen to exist. In addition, such research is necessary to determine what instances of plasticity may be created by science or society. In other words, explanatory research is needed to ascertain the extent of human plasticity or, in turn, the limits of plasticity (Lerner, 1984). From a developmental contextual perspective, conduct of such research requires scientists to alter the natural ecology of the person or group they are studying. Such research may involve either proximal and/or distal variations in the context of human development (Lerner & Ryff, 1978); but, in any case, these manipulations constitute theoretically guided alterations of the roles and events a person or group experiences at, or over, a portion of the life-span.

These alterations are indeed, then, interventions: they are planned attempts to alter the system of person–context relations constituting the basic process of change; they are conducted in order to ascertain the specific bases of, or to test the limits of, particular instances of human plasticity (Baltes, Dittmann-Kohli, & Dixon, 1984; Baltes, Smith, & Staudinger, 1992). These interventions are a researcher's attempt to substitute designed person–context relations for naturally occurring ones, a substitution done in an attempt to understand the process of changing person–context relations providing the basis of human development. In short, then, basic research in human development is intervention research.

Accordingly, the cutting-edge of theory and research in human development lies in the application of the conceptual and methodological expertise of human development scientists to the "natural ontogenetic laboratory" of the real world. Multilevel—and hence, qualitatively and quantitatively multivariate—and longitudinal research methods must be used by scholars from multiple disciplines to derive, from theoretical models of person–context relations, programs of research that involve the design, delivery, and evaluation of interventions aimed at enhancing—through scientist-introduced variation—the course of human development.

In short, in developmental contextualism there is a stress on ontological (and on epistemological, we would add) relationism and contextualization. These emphases have brought to the fore of scientific, intervention, and policy concerns issues pertinent to the functional importance of diverse person–context interactions. Examples are studies of the effects of variations in maternal employment on infant, child, and young adolescent development; the importance of differences in quality day care for the immediate and long-term development in children of healthy physical, psychological, and social characteristics; and the effects of variations in marital role strain and in marital stability–instability on the healthy development of children and adolescents.

Diversity of people and their settings means that one cannot assume that general rules of development either exist for, or apply in the same way to, all children and families. Moreover, one cannot assume, even if only small portions of the total variance in human behavior and development reflect variance that is unique to an individual or group, that this nonshared variance is not the most salient information we have when attempting to understand or enhance the quality of the lives for the person or group.

5.01.4.1 Clinical Application

With its emphasis on the relations between the individual and the context, and on the diversity of people and settings, developmental contextualism has important implications for clinical practice, including: (i) a focus on the dynamic character of behavior and pathology, (ii) specification of the impact of context on behavior, (iii) recognition of the role of strengths and assets, and (iv) utilization of multiple levels of assessment and intervention.

The developmental contextualist framework challenges clinicians to shift from a static focus on classification of the symptoms of psychopathology to a more dynamic orientation in which psychopathology is viewed as a product of the relationship between development and specific environments. The dominant diagnostic system now used by most clinicians, *Diagnostic and statistical manual of mental disorders* (*4th ed.*) (*DSM-IV*) (American Psychiatric Association, 1994), classifies problem behavior in terms of characteristic features of disorders at a single point in time, accounting for neither the development of the disorder nor the context in which it occurs (Achenbach, 1990; Cowan, 1988).

A developmental perspective requires a consideration of the meaning of behaviors at different developmental periods. Behaviors that are "normal" at one age, may be "abnormal" at another (Campbell, 1989; Sroufe, 1990; Sroufe & Rutter, 1984). For instance, enuresis is not uncommon in three- and four-year-old children but is unusual for a 10 year old. Knowing the child's developmental period may aid one in more thoroughly assessing the factors contributing to this behavior. Achenbach (1990) points out that:

> to improve our understanding of maladaptive behavior, it is helpful to view it in relation to normative sequences and achievements for particular ages. When this is done it is evident that many behavioral and emotional problems for which professional help is sought are not qualitatively different from those that most individuals display to some degree at some time in their lives. (p. 4)

A developmental perspective, therefore, encourages clinicians to consider not only what is abnormal behavior or development, but what is normal as well. An understanding of healthy development and the factors that influence both positive and negative outcomes contributes to our understanding of psychopathology (Cicchetti & Garmezy, 1993; Sroufe, 1990; Sroufe & Rutter, 1984).

The influence of development on the interpretation of behaviors is particularly evident in the area of cognitive development (Campbell, 1989). For example, if a five-year-old child whose grandfather has died says that he wants "to go where grandpa is," the clinician interprets the child's wish quite differently than a similar wish expressed by a 14 year old. The clinician recognizes that the 14 year old has a more mature concept of the meaning of death, requiring a different kind of clinical response. The behavior may look similar, but its meaning is very different at these two developmental periods. Similar characteristics displayed at various points in ontogeny may have different implications because they are embedded in a distinct developmental milieu. In short, the accurate assessment of behaviors requires an understanding of appropriate and inappropriate, adaptive and maladaptive, and expected and unexpected behaviors/skills/abilities throughout an individual's development.

An understanding of the development of a disorder, that is, how an individual found himself or herself on a particular developmental path, provides a more complete explanation of an individual's behaviors, thus allowing for a broader range of interventions. A developmental perspective provides guidance in the choice of interventions (Campbell, 1989). For instance, understanding the cognitive-developmental level of a four-year-old child, one would not be likely to use cognitive-behavioral reframing strategies during treatment. Clinicians must plan interventions that are appropriate for children at their current developmental level. Similarly, it is a widely understood phenomenon that older children can experience a greater number of differentiated emotions than a younger child. The child's developing ability to experience and identify emotions will guide practitioners in developing appropriate interventions.

A developmental contextualist framework involves not only a focus on development, but development in relation to context. The traditional *DSM-IV* approach to diagnosis/treatment does not view the behavior as the product of person–context relations. On the contrary, while it "does not claim that every category of disorder represents a mental illness, its classification system has its conceptual roots in the medical model of psychopathology, with its assumption that psychopathology is a disease located somewhere in the patient' (Cowan, 1988, p. 7). Within a developmental contextualist framework, the problem behavior is not located "within the child" (e.g., the child "has" a conduct disorder), but rather is viewed as a disturbance in the relationship or a lack of fit between the child and the settings which impact him or her. Rather than a focus on "fixing the child," developmental contextualism requires the clinician to address the fit or match between the child and the contexts which surround the child (e.g., family, school, community, culture, etc.). From this perspective, behavior is inexplicable when considered in isolation from the context in which it occurs. As an example, consider a five-year-old boy exhibiting behaviors characteristic of separation anxiety, that is, manifesting distress when away from his parents, worrying that he may get hurt if not with his parents, and refusing to sleep apart from his parents. An acontextual explanation may conclude that this behavior, while typical of a two-year-old child, is abnormal for a five-year-old child. However, if this child is living in a violent neighborhood where physical danger is a daily reality, the behaviors that he is exhibiting are not "abnormal," nor are they unexpected. To be understood appropriately and completely, this child's behavior would need to be considered as a function of his context. Spencer (1990), states that "the integration or consideration of culture and context should afford a better match between policy, practice, and positive family and child outcomes" (p. 269). From a developmental contextualist perspective, clinicians will be most effective when they understand and approach problem behavior in terms of a lack of fit between child and context.

A developmental contextual approach also acknowledges that behaviors that are adaptive in one context may be maladaptive in another context. For instance, a child's neighborhood environment may make aggressive behavior important to the child's survival, but this behavior may be maladaptive in the school environment. If one intervenes to change the maladaptive behavior witnessed at school without understanding the adaptability of this same behavior in the neighborhood, one could be doing this child a disservice. The child no longer exhibits aggressive behavior at school, but now is disadvantaged on the streets. An accurate assessment of children's difficulties requires an understanding of children within their contexts and their "problematic" behaviors within these contexts. In our example, the behavior of the child fits his neighborhood context, but does not fit well with his school context. The goodness-of-fit principle explained above implies that an intervention should work to enhance the fit of child and context. The problem does not lie solely in the environment or solely within the child. Problems result when there is a lack of fit between the individual and the context. Using a developmental contextual perspective, a clinician will gather information on the child's context to better understand the factors influencing and reinforcing the problem behavior.

Not only do children exist within their immediate contexts, but they also exist within a specific historical moment. The concept of temporality suggests that at different historical moments the person–context relation could have different meanings, that is, what is considered "normal" changes over time. For instance, a teacher living in the southern United States who is teaching poor black children to read would be viewed quite differently at different points in history. One hundred years ago such a teacher may have been viewed as a sociopath, as someone who goes against social conventions and social norms. Today that same teacher may be viewed as a dedicated, caring individual. The person–context relation not only exists in ontogenetic time, but in historical time as well.

The concept of temporality also argues for examining "tried and true" interventions such as individual counseling. Humans are embedded in the historical time in which they live. Not only do individuals change over time, but changes also occur in the wider society. Systems of assessment and intervention must be reevaluated to ensure that earlier models, developed in earlier historical moments, remain relevant and effective in the current time period. For example, the earlier exclusive reliance on individual psychotherapy has begun to give way to increased emphasis on prevention measures and group interventions. New models of treatment have begun to emerge, for example, group and family counseling and psychoeducational intervention. There is an increased emphasis on providing services through community schools. As our culture and needs change, so do our modes of intervention. In a similar manner, the types of problems presented to clinicians today are often different from those one would have found in past decades. While syndromes similar to what is now called Attention Deficit Hyperactivity Disorder have been discussed since the 1860s, the symptoms that have defined the syndrome have changed. In the 1960s, the emphasis was on hyperactivity, whereas today hyperactivity is only one aspect of the disorder; one that is not even necessary for diagnosis (Barkley, 1990).

The implicit suggestion in many of the above examples is that a child's context is not unidimensional. Children exist within a family, a peer group, a school system, a community, a culture, and a specific period in history. Similarly, their problems are not unidimensional. Their development is affected by experiences at the inner biological, the individual/psychological, the social relational, the sociocultural, and the ecological levels of organization. Given these multiple levels, accurate assessment requires integrating information about the child from multiple perspectives. Achenbach (1990) suggests five axes that are relevant to the assessment of children. These comprise parent reports, teacher reports, cognitive assessment, physical assessment, and direct assessment of the child. The axes from which one gathers information will depend upon the relevance of each axis to the child's current situation.

A developmental contextual perspective requires not only multiple-level assessment but also multiple-level interventions. Within this framework, psychotherapeutic interventions are expanded to include multiple levels of organization (i.e., biological, sociohistorical, cultural, psychological, etc.). This results in a shift in the clinician's orientation from a typical unilevel approach to intervention strategies involving multiple levels of organization. A child's development does not occur at the same rate and in a parallel fashion at each of the levels of organization. Therefore, an unevenness in strengths and weaknesses may be observed. By focusing on weaknesses only, one falls into a deficit model that focuses only on children and their "abnormal" behaviors without considering contextual factors. A developmental-contextual approach considers children within their contexts and identifies strengths as well as deficits. This approach uses an optimization framework, focusing on and building on strengths to maximize a child's full development. The clinical intervention, then, will focus on the relationships among the levels of organization and therefore will be multimodal. While a child may manifest a weakness at one level, for example, the inner-biological level, he or she may be functioning well at another level, for example, the social relational level. Intervention can occur at any level and, given the interconnectedness of the levels, will help to promote growth in other levels.

The implications of the interconnectedness of the levels (i.e., plasticity) are evident in the research on resilience. The resilience literature clearly demonstrates that children have "self-righting tendencies that move children toward normal development under all but the most persistent adverse circumstances" (Werner, 1990, p. 112). Werner (1990) identifies three areas of protective factors that may contribute to a child's resilience. These include:

> dispositional attributes of the child that elicit predominantly positive responses from the environment, such as physical robustness and vigor, an easy temperament, and intelligence; affectional ties and socialization practices within the family that encourage trust, autonomy and initiative; and external support systems that reinforce competence and provide children with a positive set of values. (p. 111)

These protective factors are found at various levels of organization, for example, dispositional attributes are characteristics of the child, and are, therefore, found at the individual/psychological level, while affectional ties are located at the social relational level of organization. Behavioral change, then, is the result of the impact of both contextual and organismic characteristics on the individual's current functioning. However, as the literature on risk and prevention demonstrates, contextual and organismic factors do not interact in an additive or linear manner, but in a multiplicative way (Sameroff, 1996). It is therefore imperative that a clinician appreciate the complex and continually changing interplay between individuals and their contexts when engaging in clinical interventions.

In essence, plasticity implies that interventions are not fruitless endeavors and that poorly functioning individuals are not doomed to remain poorly functioning if an intervention can be developed that addresses a strength. While it is true that development may be constrained by past developments and current contextual conditions, plasticity implies that humans do have the potential for change across the life-span (Sroufe, 1990; Sroufe & Rutter, 1984). Clinicians can help to remove the constraining aspects of the child's context. To optimize the effects of an intervention, the clinician must address the contextual constraints at all levels of organization. For example, a homeless child who acts out in school requires a more complex diagnosis than that provided by the diagnostic label "conduct disorder," and a treatment plan more comprehensive than that offered by a unilevel intervention such as "insight-oriented therapy," or "pharmacological treatment" (Walsh, 1992; Walsh & Buckley, 1994). This broader view of assessment and intervention planning requires that a single practitioner, for example, a psychologist, take into account the various perspectives of the child's behavior offered by different professionals. Cowen (1984) argued compellingly for a more integrated approach to practice:

> Although most mental health professionals are knowledgeable about the nature and assessment of human adjustment, they are not Renaissance persons with exhaustive knowledge of complex feeder-domains such as education, sociology, environmental planning, economics, family relations, architecture, public health, epidemiology, and social ecology, which contain significant knowledge about factors that relate to human adjustment. The points to stress are that: (a) the potential generative base for primary prevention work is much broader than the mental health fields as classically designed, and (b) in the long run, accessing and harnessing important bodies of generative information calls both for new alliances between mental health professionals and members of the other disciplines and new types of training that cut across traditional disciplinary lines. (p. 487)

The concept of multiple levels of organization, then, implies not only multiple levels of assessment and intervention by clinicians, but also collaboration among professionals. For instance, in the example of the homeless child who acts out in school, one might have the school nurse assess their nutritional and physical needs, the teacher assess their educational needs, the school psychologist explore their emotional needs, and the parents report on their behavior outside of school and the social and economic stressors placed on them as a family. Such a collaboration would lead to a more holistic understanding of this boy's needs than would a simple diagnosis of "conduct disorder." Accordingly, the resulting intervention would also be holistic in nature, involving all of the collaborators.

In short, from a developmental contextual perspective, integrated multidisciplinary and developmental research devoted to the design of intervention programs for the person or group should be moved to the fore of scholarly concern. This integrative research and outreach must involve two other considerations: first, this research and outreach must involve collaborations among disciplines and between scholarly and community interests; and second, this research and outreach must be integrated with policies and programs.

5.01.4.2 The Need for Collaborative Research and Outreach

To be successful, these endeavors require more than collaboration across disciplines. In addition, two other types of collaboration are necessary. First, multiprofessional collaboration is essential. Colleagues in the research, policy, and intervention communities must plan and implement their activities in a synthesized manner in order to successfully develop and extend this vision. All components of this collaboration must be understood as equally valuable, indeed as equally essential. The collaborative activities of colleagues in university extension and outreach; in program design and delivery; in elementary, middle (or junior high), and high schools; in policy development and analysis; and in academic research are vital to the success of this new agenda for science and outreach for children, adolescents, parents, and their contexts, for example, their extended families, their schools, their workplaces, and their communities (Brabeck et al., 1997; Weissbourd, 1996).

Second, given the contextual embeddedness of these synthetic research and outreach activities, collaboration must occur with the people we are trying both to understand and to serve. Without incorporation of the perspective of the community into our work—without the community's sense of ownership, of value, and of meaning for these endeavors—research and outreach activities cannot be adequately integrated into the lives we are studying.

Thus, from a developmental contextual perspective, research that "parachutes" into the community from the heights of the academy (i.e., that is done in a community without collaboration with the members of the community) is flawed fatally in regard to its ability to understand the process of human development. This is the case because human development does not happen at the general level (Lerner, 1988, 1991); it does not occur in a manner necessarily generalizable across diverse people and contexts (Bibace & Walsh, 1979). Development happens in particular communities, and it involves the attempts of specific children and families to relate to the physical, personal, social, and institutional situations found in their communities. Without bringing the perspective of the community into the "plan" for research, then, scholars may fail to address the correct problems of human development, the ones involved in the actual lives of the people they are studying. And if the wrong problem is being addressed, any "answers" that are found are not likely to be relevant to the actual lives of people. Not surprisingly, these answers will be seen all too often (and quite appropriately) as irrelevant by the community.

In turn, however, if community members collaborate in the definition of the problems of development that they are confronting, and if they participate in the research process, then the obtained answers are more likely to be considered significant by the community members. This will increase the likelihood of these answers being used to build community-specific policies and programs. Moreover, community empowerment and capacity building occur by engaging in a collaborative process wherein the community places value and meaning on, and participates in, the research and outreach being conducted within its boundaries (Dryfoos, 1990, 1994; Schorr, 1988).

5.01.4.3 Implications for Policies and Programs

In order to be complete, the integrative research promoted by a developmental contextual view of human development must be synthesized with two other focuses. Research in human development that is concerned with one, or even a few, instances of individual and contextual diversity cannot be assumed to be useful for understanding the life course of all people. Similarly, policies and programs derived from such research, or associated with it in the context of a researcher's tests of ideas pertinent to human plasticity, cannot be assumed to be applicable, or equally appropriate and useful, in all contexts or for all individuals. Accordingly, developmental and individual differences-oriented policy development and program (intervention) design and delivery would need to be integrated fully with the new research base for which we are calling (Lerner & Miller, 1993; Lerner et al., 1994).

As emphasized in developmental contextualism, the variation in settings within which people live means that studying development in a standard (for example, a "controlled") environment does not provide information pertinent to the actual (ecologically valid), developing relations between individually distinct people and their specific contexts (for example, their particular families, schools, or communities). This point underscores the need to conduct research in real-world settings, and highlights the ideas that: policies and programs constitute natural experiments, that is, planned interventions for people and institutions; and the evaluation of such activities becomes a central focus in the developmental contextual research agenda we have described.

In this view, then, policy and program endeavors do not constitute secondary work, or derivative applications, conducted after research evidence has been complied. Quite to the contrary, policy development and implementation, and program design and delivery, become integral components of this vision for research; the evaluation component of such policy and intervention work provides critical feedback about the adequacy of the conceptual frame from which this research agenda should derive (cf. Lanier, 1990). This conception of the integration of multidisciplinary research endeavors centrally aimed at diversity and context, with policies, programs, and evaluations is illustrated in Figure 2.

A vision of the integration between developmental research and policies and programs was articulated in the 1970s by Bronfenbrenner (1974), and more recently by Zigler (in press). Bronfenbrenner argued that engagement with social policy not only enhances developmental research but, consistent with the developmental contextual perspective, it also augments understanding of key theoretical issues pertinent to the nature of person–context relations. Bronfenbrenner (1974) noted that:

> In discussions of the relation between science and social policy, the first axiom, at least among social scientists, is that social policy should be based on science. The proposition not only has logic on its side, but what is more important, it recognizes our proper and primary importance in the scheme of things. The policymakers should look to us, not only for truth, but for wisdom as well. In short, social policy needs science.
>
> My thesis in this paper is the converse proposition, that, particularly in our field, science needs social policy—needs it not to guide our organizational activities, but to provide us with two elements essential for any scientific endeavor—vitality and validity ... I contend that the pursuit of [social policy] questions is essential for the further development of knowledge and theory on the process of human development. Why essential? ... [Because] issues of social policy [serve] as points of departure for the identification of significant theoretical and scientific questions concerning the development of the human organism as a function of interaction with its enduring environment—both actual and potential. (pp. 1–2,4)

EVALUATION

Figure 2 A developmental contextual model of the integration of multilevel, multidisciplinary research, aimed at diversity and context, with policies, programs, and evaluations.

In short, developmental research informs and is informed by social policy. It is our contention that policy development, program design and delivery, and developmental research need to be integrated fully to optimally benefit the recipients of social programs.

5.01.5 CONCLUSIONS AND FUTURE DIRECTIONS

Developmental contextualism and the research and intervention associated with it take an integrative approach to the multiple levels of organization presumed to comprise the nature of human life; that is, "fused" (Tobach & Greenberg, 1984) relations among biological, psychological, and social and physical contextual levels comprise the process of developmental change in human life. Rather than approach variables from these levels of analysis in either a reductionistic or in a parallel-processing approach, developmental contextualism rests on the idea that variables from these levels of analysis are dynamically interactive: they are reciprocally influential over the course of human ontogeny (Lerner, 1986, 1991, 1995).

In turn, developmental contextualism provides an agenda not only for a developmental, dynamic, and systems approach to research about child and adolescent development. As well, such theory allows us to envision the possibility of promoting positive developmental trajectories in youth (Lerner, 1995). We, as clinicians, researchers, and policy makers, may actualize this vision if we remain assiduously committed to a developmental systems orientation; if we recognize the "double-edged sword" nature of plasticity that derives from the functioning of this system; and if we therefore create, through policies and programs, a "convoy of social support" (Kahn & Antonucci, 1980) across the life course of children and adolescents. Such a convoy would be a network encompassing the familial, community, institutional, and cultural components of the ecology that impacts people's behavior and development across their life.

The concepts of person, of context, and of the relations between the two found in a developmental contextual perspective are, as a set, quite complex, and impose formidable challenges on those who seek to understand the developmental bases of psychopathology and of nonpsychopathologic behavior, to derive feasible research from this perspective, and to use this conception and its associated research for the design and implementation of interventions. As we have argued, this developmental contextual perspective leads to an integrated, multilevel concept of development, one in which the focus of inquiry is the organism–environment dynamic interaction. Furthermore, such an orientation places an emphasis on the potential for intra-individual change in structure and function—for plasticity—across the life-span. Moreover, this perspective requires a temporal (historical)/longitudinal and a relational/comparative orientation to research and to intervention.

A major challenge of this perspective is the derivation and empirical testing of models reflecting the nature of dynamic, interlevel interactions across time. As we have indicated, one reasonably successful path we have taken involves the testing of the goodness-of-fit model of person–context relations. Of course, the goodness-of-fit model is not the only conception of person–context relations that may be derived from a developmental contextual orientation. There are perhaps an infinity of possible interlevel relations that may occur and a potentially similarly large array of ways to model them. Indeed, tests of other models derived from or consistent with a developmental contextual or life-span perspective have also found considerable empirical support (e.g., Baltes, 1987; Caspi & Elder, 1988; Featherman, 1985; Perlmutter, 1988).

The tests of such models will profit by triangulation of the constructs within each of the levels of analysis thought to interact dynamically within a given model. For instance, in regard to the biological/organismic-psychosocial interactions assessed within the goodness-of-fit model, biological changes could be simultaneously indexed both by more molecular (e.g., hormonal) changes, and by more molar, bodily measures. Similarly, contextual demands could be simultaneously appraised by assessing both attitudes/expectations about behavior held by a person's significant other and actual behavioral exchanges between a person and these others. Such triangulation would not only provide convergent and discriminant validation information but also better insight would be gained about whether all modalities of functioning within a level of analysis are of similar import for the development of psychopathological or nonpsychopathological functioning in particular person–context interactions.

In sum, the relative plasticity of human development across the life-span—a plasticity deriving from the dynamic interactions between organism and context which characterize human functioning—is already well documented (Baltes, 1987; Brim & Kagan, 1980; Featherman, 1983; Hetherington, Lerner, & Perlmutter, 1988; Lerner, 1984; Sorensen, Weinert, & Sherrod, 1986). Thus, a future including the sorts of directions we suggest should enrich greatly our understanding of the precise conditions promoting and constraining the development of psychopathology. Given, then, the present literature, and the promise we see for tomorrow, we believe there is reason for great optimism about the future scientific and clinical use of the developmental contextual view of the biological and social contextual bases of, on the one hand, functional, adaptive behaviors and, on the other, malfunctional, psychopathological ones.

5.02.1 INTRODUCTION

The process of piecing together a clinical formulation lies at the very center of the practitioner's craft, bridging, as it does, the issues of assessment, etiology, and intervention which inform clinical work. The skills involved in specifying the nature of the presenting problem, formulating explanatory hypotheses, determining and evaluating a test of the formulation, and translating it into a treatment plan have their roots in psychological science and art.

The assertion that there is a place for art (imagination and lateral thinking) as well as science (empirical research) in the many complex activities that contribute to the final clinical formulation, might well be regarded as contentious. Indeed those who embrace a scientist-practitioner approach to clinical psychology practice may well see it as erroneous—a matter returned to later in this chapter. Generally speaking, the formulation is a means to an end, an intervention of some kind. However, it may be an end in itself: an expert report for the courts, or an assessment for the social, health, or educational services.

The way in which clinical formulations are conceptualized, and the consequent selection of data describing the client's problem, varies not only in terms of its purpose but also (as we shall see) in relation to the theoretical assumptions of the practitioner. The process usually involves four kinds of activity, summarized by the mnemonic ASPIRE (Sutton & Herbert, 1992), which represents the stages in working up a case study and, more specifically, a clinical formulation:

(i) *Stage 1, Assessment (AS)*:
  (a) focusing on the "What?" question—that is what is/are the problem(s)?
  (b) focusing on the "Which?" question—that is which of the problems are to be addressed, and in what order?
  (c) focusing on the "Why?" question—that is why have the problems arisen?
(ii) *Stage 2, Planning (P)*: focusing on the "How?" question—that is, how are we (practitioner and clients) going to address the problems?
(iii) *Stage 3, Implementation of the intervention (I)*
(iv) *Stage 4, Rigorous evaluation (RE)*.

This framework provides a process-guide which, like the experimental method it resembles, is well suited to problem-solving. It also serves as a means of organizing this chapter, which examines each of the stages: first within a theoretical and then within a practice-oriented context.

5.02.2 THE CLINICAL FORMULATION: THEORETICAL ISSUES

The process of formulating is, figuratively speaking, like the action of a funnel containing a series of filters which represent choice and decision points. They have the function of distilling a many-sided childhood problem into a relatively brief, formal statement about one's conclusions and recommendations. The resulting formulation may serve as an expert report of some kind, or as the groundplan for a hoped-for alleviation of the presenting difficulties. Whatever its purpose, it is likely to be an amalgam of analysis, explanation, and intentions that emerge at the end of the metaphorical funnel.

The broadly based strategic decisions will have been made at the opening to the funnel, namely the chosen ideological stance (e.g, scientist-practitioner or humanist) and the theoretical model (say, cognitive-behavioral, Rogerian, or psychodynamic) adopted for the casework. Of course, the choices may not be starkly either/or, as when an eclectic style of working is preferred.

5.02.2.1 Clinical Psychology as Applied Science

At the broad end of the figurative funnel referred to earlier, is a filter influencing the clinical information that is edited in (and out) of the formulation. It involves the choice or rejection of a science-based philosophy of clinical work.

Long and Hollin (1997) make the point that the history of the scientist-practitioner stance is marked by an enduring struggle between advocates and opponents of a research-based profession—which is to say, a practice that is based on an empirically based assessment of problems, and the application of validated treatment methods which are linked (through the formulation) to theoretically coherent causal hypotheses. The reliance of the "scientist-practitioner" on empirical methods generates a model for service provision that is competency based. For Gambrill (1983) this requires:

(i) a focus on the present, which may be related to events in the past, and requires clarification by an exploration of the past (e.g., the person's learning history, deeply rooted attributions and ideologies);

(ii) a focus on describing problems (assessing them by a process of surveying, selecting, and prioritizing difficulties) and operationalizing them by means of multidimensional measurable outcomes;

(iii) a focus on multiple response systems of an individual nature (e.g., cognition, affect, and physiology) and of an interactional kind (e.g., family, school, workplace);

(iv) a focus on positive behaviors and events;

(v) a focus on the relationship between behavior and events in the external environment that elicit or maintain it.

Criticisms of the validity of such an idealized model have centered, *inter alia*, on the inadequacies of positivist philosophies of science and experimental research methodology for addressing the complexities and subtleties of individual psychopathology, or the sheer irrelevance of research for clinical practice. An example would be the attitude to formulating held by psychologists in the tradition of Maslow (1954) and Rogers (1957) whose ideas have been seminal in humanist psychology. Individuals are viewed as having an inherent need to grow. This intrinsic motivation reveals itself in the process called self-actualization.

Such a positive, optimistic (critics might say romantic) view of human nature, has little in common with the kind of formulations which are so preoccupied with analyzing and cataloging the failures or deficiencies of parents and children that they neglect to see their strengths and potential for self-directed growth. Such analyses are regarded by the severest critics as mechanistic, demeaning, and dehumanizing.

This is a view that is strongly contested (e.g., Herbert, 1987a, 1987b) when it is used in an overinclusive manner to cover all science-based practice. For those clinical psychologists who see themselves as scientific practitioners, their appeal to science is not usually restricted to the results and methods of traditional experimentation alone. The limitations of experimental methods are well known in relation to the study of human behavior: its sensitivity to minor variations in sampling and procedure, leading to failures of replication (i.e., to findings which are not robust); its confusion of aggregate effects with generalized effects (i.e., tendency to confuse an aggregate statistical effect with a general or common effect); its tendency to prefer methodological rigor over conceptual or practical experience; its liability to experimenter effects and demand factors; its neglect of contextual factors; and finally, its presumption that the experimental method is superior to the other methods regardless of circumstance (see Bromley, 1986).

Bromley (1986), while acknowledging that the case study cannot replace other experimental methods, is of the opinion that certain problems, notably the issues faced by clinical psychologists, lend themselves to this method of investigation. He provides an invaluable guide to the effective use of the case study as a method of inquiry and formulation. He suggests that the findings of scientific case studies depend, not so much on the logic of statistical inference, but rather on the logic of substantive reasoning. Case studies, he proposes, can generate and test abstract and general theories; when used systematically they are capable of combining basic and applied science—not only psychological, but also legal science. Bromley argues plausibly for the application of what he calls a quasi-judicial approach to clinical problems, drawing on the knowledge base of legal science for guidance on (among other things) rules of evidence. Some practical implications are studied later in this chapter.

With regard to the other criticisms of the irrelevance of research, Cohen's (1977, 1979) surveys indicated that 40% of mental health professionals thought there was no relevant research to inform clinical practice, while the other 60% were of the opinion that less than one-fifth of research articles had any applicability to professional settings. It is perhaps surprising that research and practice should be thought of by so many as mutually unhelpful or, at worst, incompatible, given that problem-solving is an essential ingredient of both of them (see for different sides of the argument, Meehl, 1971; Peterson, 1976; Shakow, 1978; Watzlawick, Weakland, & Fisch, 1974).

Long and Hollin (1997) point out that the growth in clinical research which was a concomitant of the burgeoning of learning-theory-based (behavioral) methods of intervention, from the 1950s onwards, led to the development of innovative and flexible research designs and methods (see Barlow & Hersen, 1984). This meant that practitioners could link more confidently, and in logical fashion, their application of particular therapeutic methods/techniques to an empirically based theory of dysfunctional behavior. This relationship could then be clearly enunciated in a formulation and, furthermore, validated by means of $N=1$ designs. It has to be said that by no means was everyone convinced by such confidence in the logical linkage between learning theory and its therapeutic methodology (e.g., Erwin, 1979; Power, 1991). Another development that broadened the appeal of the scientist-practitioner viewpoint was the growing sophistication and respectability of qualitative research methods (e.g., Marshall & Rossman, 1989). Certainly, it has gone some way to mitigate the accusations of triviality aimed at the kind of research that is narrowly or obsessively "quantiphrenic" in its definition of legitimate methodology.

Despite such developments, reservations about the validity of a scientist-practitioner approach to generating clinical formulations continues to inform debate on the appropriate model for practice and, thus, training in the profession (see Andrews, 1989; Gambrill, 1990; Pilgrim & Treacher, 1992, for discussions of these issues).

5.02.3 THE ASSESSMENT PROCESS

The filters mentioned above play a critical role in determining what information is pertinent in the investigation of the client's problems, and which assessment methods will generate the clinical data necessary for an intervention. As the funnel narrows, so does the focus of the questions: "What?," "Which?," "Why?," and "How?" that give direction to the assessment.

The final "How?" query leads to the strategic formulation of a precise treatment plan, and the tactical specification of methods/techniques for bringing about change.

5.02.3.1 The "What?" Question

Hepworth and Larsen(1990, p. 155) define this question in terms of "gathering, analyzing and synthesizing salient data." But what constitutes salient data? Answers to this question are likely to vary (alarmingly, some would say) according to the clinician's therapeutic model and its theoretical assumptions. At its most basic is the issue of what constitutes a priority in any clinical investigation: description or categorization—a debate centering on the concepts of assessment and diagnosis. Clinical psychologists tend to prefer the term "assessment" to "diagnosis"—a word that means to distinguish, and is essentially about classification. An assessment conveys the broader descriptive implications of an investigation or analysis of the causes or nature of a condition, situation, or problem. These implications are supposed to be neatly encapsulated within a diagnostic label, but, in reality, seldom are.

The differentiation of the "What?" and "Why?" questions is somewhat artifical as they tend to merge as the assessment progresses. When the collection of sufficient data allows for it, there is a formal explication: the formulation of a set of explanatory hypotheses describing the determinants, historical and current, of the problem. These, in turn, generate possible solutions to the client's difficulties.

5.02.3.2 The "Which?" Question

One of the clinicians' first choices is where to concentrate their attention in what may present itself as a welter of conflicting claims, complaints, and accusations. Some of the problems will reside mainly within an individual (e.g., fear) but even then they will have repercussions. The individual's parents (or partner) worry about his or her suffering. Or the problems put constraints on the activities of the family, as when holidays are not possible because (say) a mother is agoraphobic, feeling anxious about leaving the house, and panicky in a crowded shopping center.

Other problems arise from the relationships and interactions (such as the give-and-take transactions) between people. For example:

(i) mother–father: disagreements about the children, quarrels over decisions, other marital difficulties;

(ii) parent(s)–child: management difficulties, disappointments over the child's achievements or lack of them;

(iii) child–parent(s): resentments about being "babied," complaints about unfairness, or favoritism;

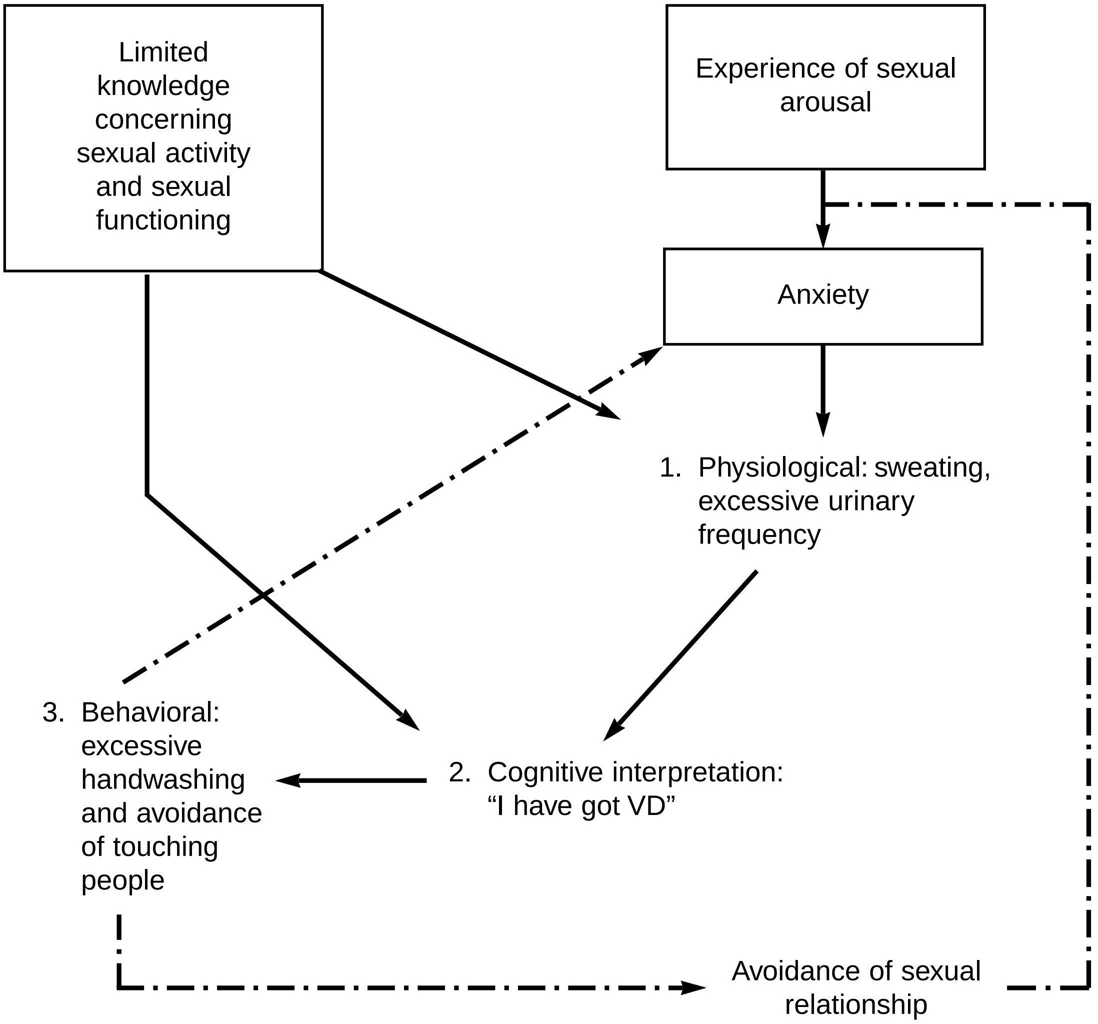
(iv) child–child: sibling rivalry, jealousy.

As the assessment proceeds, the client(s) may be one of these persons (a school-refusing child), two of them (the embattled parents), or all of them (the family). The practitioner might even have to work more widely in the neighborhood, at the school, or with other agencies in the community. Who the client is, is in fact a vexed question, as can be seen when examining systemic ideologies.

5.02.3.3 The "Why?" Question (Etiology)

Etiology—the study of causes of disease—has served physical medicine well. Research firmly rooted in scientific philosophy and methodology has led to an impressive armamentarium of rational treatments which have done much to reduce human suffering. Not surprisingly, psychologists and psychiatrists entertained high hopes of emulating their physician colleagues by endeavoring to work within a scientific and (notably, for psychiatrists) a medical framework. The complexity of psychiatric and psychological problems has led to great confusion in the analysis of causes (Herbert, 1994a). There is an all-too-human tendency to oversimplify and think of causality in linear, univariate terms: *A* causes *B*; *B* is the effect of *A*. However, there is no limit to the analysis of causes. One finds not a single antecedent, not even a chain of antecedents, but a whole interlacing network of them, as indicated by this complexity in Fielding's formulation of an adolescent patient's obsessional anxiety (Fielding, 1983) (see Figure 1).

One point of agreement that appears to emerge from the plethora of findings about problems like these is their multicausality. Mayer-Gross, Slater, and Roth (1955) make the point that in medicine it is necessary to deal with causes of all kinds, not just those that are



Limited knowledge concerning sexual activity and sexual functioning
Experience of sexual arousal
Anxiety
1. Physiological: sweating, excessive urinary frequency
2. Cognitive interpretation: "I have got VD"
3. Behavioral: excessive handwashing and avoidance of touching people
Avoidance of sexual relationship

Figure 1 Clinical formulation of obsessional hand-washing in a 16-year-old male adolescent. (The Practice of Clinical Psychology in Great Britain, by D. Fielding (1993) Chichester: Wiley Copyright 1994 by Wiley. Reprinted with permission.)

both necessary and sufficient. In searching for a cause of some phenomenon, we are really searching for a quantitative relationship. If *A* is the necessary and sufficient cause of *B*, then there is a one-to-one relationship between *A* and *B*. If *A* is a necessary but not sufficient cause of *B*, then there is no *B* without *A*, but *A* may be combined with *X* or *Y*, instead of with *B*. If the variety of these *X*s and *Y*s is great, the causal relationship, though it still exists, is thereby attenuated. If *A* is neither necessary nor sufficient, then there are *A*s without *B*s and *B*s without *A*s, and the strength of the causation will depend on the proportionate relationship between *A*/*B* and *A* on the one hand and *B* on the other.

Mayer-Gross et al. (1955) observe that it is not difficult to founder in a causal network. We are less likely to do so if we take into account the quantitative aspect of causation. It is at this point that so much psychological thinking loses cogency and direction. Quantitatively important causes are tangled in a knot of others with only a slight or entirely unknown quantitative relationship with the effects we are interested in.

The reality for psychologists and psychiatrists is the complex, multivariate nature of most of the phenomena they study. In their clinical formulations, they have to take into account both intrinsic (organismic) factors and extrinsic (environmental) influences. The latter may consist of direct (proximal) and indirect contemporary (contextual), as well as indirect predisposing (organismic) and historical (distal) determinants (see Figure 2).

The tendency for clinical child psychologists to work in multidisciplinary teams which include, *inter alia*, psychiatrists, speech therapists, and social workers, or in close collaboration with medical colleagues (e.g., GPs and

pediatricians) is understandable when we look at this complexity of physical, social, economic, and psychological influences on psychopathology. Behavior results from a very complex interaction of psychosocial and biological determinants (Herbert, 1991a). The important caveat in relation to clinical formulations is not to neglect, through a commitment to a psychogenic model or biogenic theory of psychopathology, the possibility of complications from the other side of the causal equation.

The trouble with the search for causal reasons is that there are several levels of explanation which may apply to a particular problem. This is illustrated by a young child who has a learning problem which is affecting her ability to read. On top of this, she has certain behavioral problems, as constant failure is causing her morale to sink lower and lower. Diagnostic tests carried out by the psychologist show that she has a visual-perceptual handicap. Remedial treatment is available to help her overcome her reading problem. The remedial teacher could teach her to recognize words and their meanings through the medium of her other sensory modalities. Here, the visual handicap is one explanation of the reading difficulty. Some clinicians would rest content with this level of causal explanation—the so-called instrumental level of explanation. The explanation is sufficiently precise to be instrumental in planning some therapeutic measures to mitigate the cause–effect sequence of events. Or it may simply be instrumental in providing the individual with a satisfactory account of some event. It is sufficient in that it explains, and raises no further questions in his or her mind.

While this explanation provides an account of an important antecedent condition in the problem—in this case the visual-perceptual handicap—other clinicians might claim that the diagnostician should search for "original" or "deeper" causes. In this case they would feel it necessary to determine whether the visual problem is due to organic causes, perhaps resulting from complications during her birth or a genetic predisposition.

5.02.3.4 The "How?" Question

The assessment of causal influence should, in an ideal world, inform the choice of therapeutic strategy or some broader-based community intervention. Only too often the assessment data, like the occupants of Procrustes' bed, are made to fit the favored therapeutic model. There is an implied suggestion that a particular approach can be applied to all problems. Sadly, faith, rather than evidence, is mostly what is on offer to support the more Panglossian prospectuses. The most durable and popular of the psychological therapies for children have been relationship therapy, play therapy, child analysis, behavior therapy/modification, and the relative newcomers cognitive behavior therapy, behavioral and nonbehavioral family therapy, and behavioral parent training. There is some overlap in process (if not in name) between the various psychological therapies, but they are essentially different, not only in their outward and visible manifestations, their "technology," but also, as one would expect, in their underlying theoretical rationale and, consequently, their goals.

Although there is no one coherent theory of therapeutic change, there is some overlap in goals. For Kazdin (1987, 1988), the goals consist of improving adjustment and functioning in both intrapersonal and interpersonal spheres and reducing maladaptive behaviors and various psychological (also physical) complaints. Even when there are differences of emphasis in therapeutic goals, all treatments share the objective of producing change.

Any form of therapy (be it psychotherapy or behavior therapy) involves psychological influence—implicit or explicit—deployed in the setting of a relationship between client and therapist. The dichotomy drawn between interpersonal and relationship factors on the one hand, and technique on the other, seems somewhat forced; indeed, it may be false, because it is doubtful whether these two major components in the therapeutic enterprise can ever be isolated in pure and separate cultures.

5.02.4 EXPLANATORY MODELS

One can say with confidence that there are considerable variations on the theoretical themes that inform similarly-named treatments. Different theories of family process generate different schools of family therapy (Herbert, 1997a; Vetere & Gale 1987). Play therapy also draws on different nuances of childhood "psychopathology" theory, and thus takes different forms (including active play therapy, release therapy, and the play interview) and is being applied on a dyadic, one-to-one basis (e.g., Axline's approach) or in a group format (e.g., Filial therapy).

Psychological therapies can be differentiated on two major dimensions:

(i) a passive vs. an active role on the part of the therapist;

(ii) the method (technique) vs. relationship as the main agent for change.

They can further be distinguished in terms of five attributes:

(i) the goals (or purpose) of therapy, for example, supportive, prescriptive, or exploratory;

(ii) the means by which goals are sought; this encompasses the theoretical rationale, for example, behavioral, cognitive, client-centered, or psychodynamic, (in child therapy these approaches may be mediated by talking to, playing with, rewarding the child or rehearsing skills with him or her);

(iii) the modality of therapy, for example, individual, group, couple or family;

(iv) the level of expertise of the therapist;

(v) the adoption of an expert or collaborative approach to clients.

The range of choices of individual psychotherapies—notably in the case of adolescents—constitutes a "menu" which almost rivals the feast available to adults: psychodynamic, client-centered, behaviorally oriented psychotherapy, communication, drama, role-construct, social system, multimodal, transactional, existential, gestalt, to mention a few. These are relatively broad approaches or perspectives. When we come down to techniques a conservative estimate suggests that there are more than 200 to choose from (Kazdin, 1988; Tuma, 1989).

What does such profusion mean? The sceptic might say that when so many treatments are in use, applied often to the same kinds of problem, it means that we lack a firm conceptual grasp of causation. In any event does it matter if the critics are correct in saying that psychotherapy has no adequate unifying theory? Why not simply consider treatment as a technology without recourse to any distinctive foundational theory? Erwin (1979) is of the opinion that we cannot afford to ignore the study of theoretical foundations. He states that an adequate theory might provide some important practical benefits. For example, if better clinical techniques are to be developed, it will be helpful to know exactly which features of the successful techniques are therapeutically productive and why, also which techniques have a greater antecedent likelihood of success than do others. This is a cue to look briefly at the major therapeutic models and the formulations which predicate their use.

5.02.4.1 The Medical Model—Diagnostic Formulations

Nowhere is the influence of medical ideologies in clinical child psychology more pronounced than in the reliance on classification and the diagnoses of children's psychological problems. Underlying the creation of classificatory systems (e.g., the *DSM-IV* (American Psychiatric Association, 1993) and *ICD-10* (World Health Organization, 1992) and taxonomies of "symptoms" is the assumption that specific syndromes (disease patterns) with identifiable and specific causes (etiologies) can be diagnosed. It might be added that the only justification for applying diagnostic categories to children is that not only should they imply reliable descriptive criteria and clear causal theories, but also that treatment implications should flow from the choice of label.

The particular issue of reliability in the assignment of diagnostic categories remains a contentious one (Zwick, 1983). This is a potentially major stumbling block as the validity of any system of measurement or classification depends, in large part, on its reliability. Achenbach and Edelbrock (1989) made the point that in order to be effective, formal diagnoses (and diagnostic formulations) require reliable taxonomic distinctions so that we can link cases that share useful similarities and to distinguish between cases that differ in important ways. The various *DSM* criteria for childhood psychopathology consist mainly of lists of behavioral-emotional problems rather than clearly identifiable physical abnormalities, and they are problems to be judged as present or absent. Unfortunately, as the authors state:

> most of these problems are not easily categorized as present or absent. Instead they vary with the child's age, situation, and interaction patterns. Whether the child is deemed to have a particular problem depends on when and how the child is assessed. Because many of the problems for which mental health services are sought occur outside the clinic setting, assessment typically requires information from people other than clinicians, such as parents and teachers. The different situations in which they see the child and the different roles they play with respect to the child are bound to affect what they report. (p. 55)

Achenbach, McConaughty, and Howell (1987) carried out a meta-analysis of 269 samples (in studies published from 1960 to 1986) of correlations between different informants (parents, teachers, trained observers, mental health workers, peers, and the children themselves) reporting children's behavioral-emotional problems. The mean correlations between informants playing similar roles with respect to the children, including pairs of parents, teachers, mental health workers, and trained observers ranged from 0.54 (mental health workers) to 0.64 (pairs of teachers) with an overall mean of 0.60. This substantial, although far from perfect, level of agreement dropped considerably when informants had different roles with the children. The mean correlations ranged from 0.24 (between parents and mental health workers) to 0.42 (between teachers and direct observers) with an overall mean of 0.28—statistically significant but low. With regard to the self-reports and others' reports of the same child, the mean correlation of 0.22 is statistically significant but even lower.

With regard to the face-validity of psychiatric categories for professionals, a survey of 1000 qualified or trainee American psychiatrists by Jampala, Sierles, and Taylor (1986) is of interest. A full 48% did not believe in the validity of the *DSM-III* criteria and 55% would have ceased to use it, had it not been required. They felt that the diagnostic categories failed to accommodate almost half of their patients. This is a serious indictment since the salient point about a classification-based formulation is that it needs to be comprehensive and to group individuals according to their distinguishing problematic behavioral, cognitive, and affective patterns. In the taxonomics of childhood disorder there is probably no better example of the difficulties, contradictions, and confusions than the criteria for attention deficit hyperactivity disorder and hyperkinesis provided in the *DSM-IV* and *ICD-10* systems, respectively.

Reviews of the literature suggest that despite interesting correlations between "problematic" childhood behaviors, the vast majority of "disorders" (it is difficult to avoid medical usage) cannot be conceptualized—except figuratively—as disease entities. Unlike many of the acute physical illnesses the structure of a presenting psychological problem, the etiology of the problem, and the implied treatment do not closely map on to each other (Sturmey, 1996). Achenbach and Edelbrock (1989) conclude a review of these issues by acknowledging that there is little agreement about the proper nature and role of diagnosis with respect to the psychopathology of children.

Whatever the reliability and validity of diagnostic schemes, there is an objection raised by many psychologists (and psychiatrists) to what they see as invidious "labeling" and stigmatizing of individuals by reducing complex "life problems" to a restrictive medical category. There is concern about how parents', teachers', and children's attributions, perceptions, and actions are affected by being told by an expert that the child has a disorder of some kind. Such reification may absolve parents from any sense that they can influence the difficulties. It may "tell" the child that they are different from other children, and furthermore, not in control of their actions—a pessimistic message to instill in someone at an impressionable stage of life. Most worring is the absence of a clear relationship between most global diagnostic classifications applied to particular children and any clear etiology or focused therapeutic/remedial program of action (Herbert, 1964).

The reality is that childhood signs of psychological abnormality are, by and large, manifestations of behavioral, cognitive, and emotional responses common to all children. Their quality of being dysfunctional lies in their inappropriate intensity, frequency, and persistence; most childhood disorders differ in degree, rather than kind, from normal behavior. The exceptions to this generalization are rare (see Herbert, 1994b). That generalization does, however, raise ethical problems for the practitioner. Leung (1975) observes that, whereas the medical model provides a reasonably unambigious ethical rationale for treatment by an *a priori* standards of "health" and "pathology," behavioral definitions tend to construe abnormality as not in itself different from normal behavior. If abnormal behavior is considered learned, therapists are involved in making, or at least concerning themselves with, value judgments that some other behavior would be preferable—a social, subjective, and therefore potentially prejudicial decision. This leads inexorably to the following questions, the answers to which have the status of ethical imperatives for the therapist as agent of change: "To whom is the behavior undesirable? Is it *really* in need of modification, and if so, to what must it reasonably change?"

Of course, the medical model has produced highly effective aids to the treatment of childhood psychopathology, but it also raises a moral dimension, particularly in the use of potentially harmful and/or addictive medication. As in the case of "owning" a diagnostic label, the attributions for a child's locus of control that follow from the regular use of drugs prescribed to make him or her "quieter" and "better behaved" are matters of concern.

A pitfall of using diagnostic classification in clinical formulations is the tempting but illusory impression it can give the practitioner of having explained the problem, when all it amounts to is a renaming process, and consequently a "thought-stopper." Take the boy who is always on the go, fidgets, is endlessly flitting from one activity to the next, and is very difficult to manage. The teacher who refers him to the clinic wishes to have an answer to the question: "Why does the child have such poor concentration, and why is he so disruptive—forever interfering and going "off task," defying my requests?" The report that comes back states that the child is ADHD (hyperactive). If asked to explain this diagnosis ("How do you conclude that the child is hyperactive?"), the clinician is quite likely to have to return to the observations they were asked to explain in the first place: "Because the child is inattentive, fidgetty, overactive, and noncompliant." Many of the explanatory constructs in the mental health field are tautologies of this kind.

Ross (1968) finds parallels between the practitioner's preoccupation with classification and the fairy tale in which the opportunity for a princess to live her life happily ever after depends on her discovering the name of an ill-tempered creature. She goes to great lengths, and upon achieving her goal earns her salvation. Ross calls the preoccupation with seeking a name for a child's problem in order to "save" it, the "Rumpelstiltskin fixation." It should not be the primary task of psychologists, he admonishes, to identify a disease by its signs and symptoms, but rather to get on with their real job of describing children and their difficulties in terms adequate enough to bring effective interventions into play, and with them, positive outcomes.

In the real world, of course, the clinician does not always have the luxury to be too pedantic (or precious) about such matters. While there may be misgivings about labeling children, there may be compelling policy, planning, service development, resource mobilizing, and research reasons for doing so. For the private practitioner there is the consideration that insurance companies insist on formal diagnoses.

5.02.4.2 The Statistical Model—Multivariate Analyses

Statistical (and particularly factor analytic) methods have proved popular in the search for clusters of problems which might lend support to the classifications built upon clinical observation and experience. What is advocated is an empirical approach which involves a minimum of assumptions and constructs regarding the causation of behavioral disorders. Despite the range of instruments that is available and the number of dimensions measured by these instruments, two major dimensions emerge from most analyses: problems of an *undercontrolled* type (variously referred to as conduct disorder, aggressive, externalizing, acting out) and an *overcontrolled* type (emotional disturbance, personality disorder, inhibited, internalizing, anxious) (Quay, 1986).

There is some limited overlap between behavioral dimensions (obtained by psychological measurement and factor analysis) and *DSM* criteria (see Quay, 1986). Their limitations with regard to implying causation or generating individual treatment options are much the same, although Achenbach and Edelbrock (1989) have illustrated ways in which the Child Behavior Checklist and Child Behavior Profile can be put to practical use, by providing quantitative descriptions of behavioral competencies and problems at various levels.

5.02.4.3 The Psychoanalytic Model—Psychodynamic Formulations

The "psychodynamic approach" is a superordinate title for a variety of therapeutic developments which had their origins in Freudian psychoanalysis (Lee & Herbert, 1970; Rycroft, 1966; Tuma, 1989). The term encompasses theories of personality and therapies which assume the existence of unconscious mental processes, and which concern themselves with the elucidation of motives and the transference relationship, that is, the transfer on to the therapist of attitudes, longings, and feelings attaching to significant others.

Farrell (1970), in his synoptic account of psychoanalytic doctrine, states that the classical Freudian theory is primarily a theory about mental energy. This takes two fundamental forms which, in the early and better-known version of the theory, are the sexual and the self-preservative; and this energy goes to determine the character of the stages (oral, anal, etc.) through which the mind develops. In the course of this development the mind becomes differentiated into the structures of id, ego, and superego, cut across by the critically important barrier separating the unconscious from the preconscious elements of the mind. The total balance and distribution of energy is controlled by the mechanisms of defense, such as repression, regression, displacement, and so on. Where this control had not been satisfactorily achieved in the past, the repression barrier keeping the unconscious instincts of the system at bay is apt to break down under frustration. The unconscious comes to the surface in the compromise form of neurotic or "acting out" symptoms.

The neo-Freudian ideas of Melanie Klein (1975) have a different emphasis. This is primarily a doctrine about the "object relations" an infant forms (especially with the objects of mother and her breast) and about the internal world of the infant's unconscious fantasies. From the outset, infants experience the anxieties of living and are faced, in particular, with the breast that both satisfies and frustrates them. They deal with these difficulties by means of the defenses of introjection, projection, and splitting. Thus, to begin with, infants introject the breast (i.e., incorporate it in fantasy) and split the good breast from the bad. The character of infants' object relations—their good or bad quality—and the extent to which they get through various early stages satisfactorily are all of crucial importance to them. Therefore, the liability of the grown-up man or woman to break down, and the character of his or her collapse when it comes, are critically dependent on what happens inside the infant during the first year of life.

Therapists working with a psychodynamic model give much more weight to intrapsychic events in their formulations than behavior therapists because their perspectives are characterized by different epistemologies. These differences are illustrated in case history formulations from the mid-1920s. Where Little

Hans, with his deeply symbolic fear of horses, became the much-quoted standard-bearer of the psychoanalytic paradigm, Little Peter (age 2 years 10 months at the beginning of his treatment for a fear of rabbits) became the exemplar of the behavioral paradigm (see Freud, 1926; Jones, 1924).

Freud was essentially a proponent of *verstehende* or "understanding" psychology; he wished to answer the "whys" of human conduct. Despite his training in medicine and research work in physiology he was not content with the "mere" observation of surface behavior or with the investigation of neurophysiology; he was determined to explain the mental mechanisms underlying complex sequences of behavior. He wished to account for the whole of human mentation at the psychological level of explanation—formulating the experience of the neurotic patient, in terms of the meaning of his/her symptoms.

Psychoanalytic formulations (whatever the present-day school of psychoanalysis) tend to be derived from extensive arrays of molar segments of self-report and verbal exchange with the therapist, collected (usually) over a considerable period of time. The records of the therapy would be copious. By way of contrast, the clinical child psychologist, in scientific mode, is concerned with a deliberately curtailed and simplified series of events in the life of his/her clients. Analysts see superficiality in such parsimony—a misdirection of "gaze" which will simply result, if only presenting "symptoms" are removed, in other symptoms (the outer and visible signs of the "real" underlying difficulties) coming to the surface. This is the disputed phenomenon called "symptom substitution."

There have been intense debates about the status of psychoanalysis and its many-faceted progeny, the "psychodynamic approach." It is difficult for the hermeneutic framework of the psychodynamic model to be integrated within that of the scientist-practitioner approach (see Farrell, 1970; Fisher & Green, 1996; Long & Hollin, 1996; Pumpian-Mindlin, 1952; Rachman, 1963; Wachtel, 1977; Webster, 1995). And yet Freud's aim was to establish a "scientific psychology," and his wish was to achieve this "metapsychology" by applying the same principles of causality as were at that time considered valid in physics and chemistry.

For Farrell (1966), the fact that no usable "correspondence rules" (i.e., operational definitions) had been constructed for any of the large numbers of concepts of psychoanalytic theory, was a major stumbling block in testing its validity. If patients ask what terms like "repression" mean or what phrases like Klein's "fantasized incorporation by the infant to the breast" indicate, there is likely in Farrell's words (p. 22) to be "elucidation by means of, in part, the concept of psychic energy . . . an explanation *per obscurius*, or an abrupt plunge into psychological absurdity."

Rycroft (1966) maintains that what Freud was engaged in was not explaining the patient's symptoms causally, but understanding them in order to give them meaning. This was not the scientific procedure of elucidating causes, but the semantic one of making sense of them. He says it can be argued that much of Freud's work was discovering that neurotic symptoms are meaningful, disguised communications, but that owing to his scientific training and allegiance, he formulated his findings in the conceptual framework of the physical sciences.

Psychoanalytically-oriented psychotherapy or play therapy with children is a less ambitious and demanding form of psychoanalysis than the form used with adults. Here the relationship between child and analyst is a means whereby therapeutic goals are achieved. The child is helped, by means of play and therapeutic conversations:

> to undo the various repressions, distortions, displacements, condensations, etc., which had been brought about by the neurotic defence mechanisms, until, with the active help of the child, the unconscious content of the material is laid bare. (Anna Freud, 1946, p. 71)

5.02.4.4 The Personality Typology Model—Trait Formulations

The personality structure approach to assessment postulates personality dimensions, in part inherited, that influence what and how children learn as they grow up. It has been observed that every person is, in certain respects, like all other persons, like some other persons, and like no other person. The nomothetic disciplines which favor the philosophy and methods of the exact sciences have been applied to the study of the highly generalized personality attributes (types and traits), while idiographic methods have been used to explore the aspect of uniqueness and individuality. According to one theory, the possession of particular combinations of personality characteristics (e.g., extraversion/introversion and neuroticism) determine whether certain children are predisposed to acquire dysthymic or conduct disorders (Eysenck, 1967). Given an extreme position on the continuum toward introversion or extraversion (which has implications for the individual's conditionability) and a labile or reactive autonomic nervous system (a high rating on neuroticism), the child is thought to be particularly susceptible to acquiring phobic anxiety through ease of social conditioning, or a conduct disorder because of its relative failure.

There are several limitations to the use of personality typing in the formulating process. The situations sampled are restricted in range: for example, behavior at home or at school. Furthermore, assessment methods tend to emphasize verbal behavior such as interviews, self-reports, and questionnaires. In the applications of such methods of assessment, personality differences in behavior across settings are seen as error variance in an imperfect measurement system. Greatest weight is placed on the initial assessment and diagnosis rather than on repeated, ongoing assessments. In personality-type assessments the person's behavior is compared with statistical norms.

The practical implications of an assigned personality "diagnosis" or profile for a treatment plan are limited (Herbert, 1965; Moore, Bobblitt, & Wildman, 1968). The issue of situation specificity makes it difficult to make predictions or arrive at precise conclusions of an individual kind, on the basis of generalized constructs. On the other hand, the early assessment of temperament—the constitutional aspects of personality—into its major categories "difficult," "easy," or "slow to warm up" and its behavioral referents, may allow preventive clinical work to be planned (Thomas, Chess, & Birch, 1968). A mismatch between parental attributes and the child's temperamental style can result in an extended series of mutually unrewarding interactions which are foundational for later relationships. They can lead to depression in mothers (in particular) and faulty or incomplete socialization in children (see Iwaniec, 1995).

The idiographic disciplines, such as biography, literature, and history, endeavor to understand and illuminate some particular event. The use of idiosyncratic and subjective projective techniques is an example of this tradition in clinical work. The case study is an exemplar of what Allport (1937) believes is an ideal combining of the idiographic and nomothetic approaches for the fully rounded appreciation of the person and their situation. In the view of Bromley (1986) it is the bedrock of clinical investigation, and part of the scientist-practitioner's armamentarium.

5.02.4.5 The Systemic Model—Family Therapy Approaches

An individual in a family system is affected by the activities of other members of the family. Whereas the traditional treatment model tended to identify the nominated client or patient as the unit of attention (e.g., the child referred to the child guidance clinic), the focus of assessment in the light of this interactional frame of reference is far more broadly conceived. Thus the focus of help is not necessarily prejudged as only the child who was referred; rather, the unit of attention becomes the family (or one of its subsystems).

The systemic perspective is well-illustrated in family therapy, a fashionable approach to childhood psychological disorder. There is no one therapeutic entity under the rubric "family therapy," but several schools or paradigms. For example, there is the structural school of Minuchin and his colleagues (Minuchin, 1974). Strategic family therapy has its origins in the Palo Alto research group led by Bateson (e.g., Bateson, Jackson, Haley, & Weakland, 1956; Jackson, 1957). Humanistic, existential therapies of the 1960s, such as Gestalt therapy, psychodrama, client-centered therapy, and the encounter group movement, influenced the theory and methods of various experiential family therapies—challenging the positivist tenets of the more problem-focused schools of family therapy (e.g., Satir, 1967). Behavioral family therapy and cognitive-behavioral therapy have their intellectual roots in social learning theory (Patterson, 1982). Psychodynamic and object relations perspectives, derived from psychoanalytic theory, found an exponent in Ackerman (1958). The intergenerational perspective, which looks beyond the immediate family circle and enlists the cooperation of others in resolving the family's distress, is associated with the names of pioneers such as Bowen (Bowen, 1966). If this were not a daunting enough choice, the clinican could look to the Milan Systemic Approach, the McMaster Family Model, Problem-solving Therapy, Brief Family Therapy, or Social Network Therapy (see Herbert, 1997a). Piercy, Sprenkle, and associates (1986) describe 54 technique skills for the major family therapies.

As with other therapeutic models the paths on the journey toward making a formulation are many and not always clearly signposted. What does unite most family therapies as they engage in their divergent formulations and treatment strategies, although at a high level of abstraction, is a perspective which requires that children's problems be understood as the consequence of the pattern of recursive behavioral sequences that occur in dysfunctional family systems. The systems approach, as it translates to family work, embraces the concept of reciprocal/circular causation in which each action can be considered as the consequence of the action preceding it and the cause of the action following it. No single element in the sequence controls the operation of the sequence as a whole, because it is itself governed by the operation of other elements in the system. Thus, any individual in a family system is affected by the activities of other members of the family, activities which his or her actions or decisions (in turn) determine. This recursive element makes the formulation of what is cause and effect extremely complex.

Family therapists, whatever their methods and theoretical underpinnings, tend to believe that behavior problems in children are symptomatic (or, indeed, artifacts) of dysfunctional family life; the goal of treatment is therefore the improvement of family functioning. The members are encouraged, by a variety of therapeutic strategies and homework tasks, to understand the alliances, conflicts, and attachments that operate within the family unit and to look at themselves from a fresh perspective and to seek alternative solutions to their dilemmas.

The family, as a small group, can be observed and assessed on a variety of dimensions: patterns of communication, cohesion and processes of decision making (see Vetere & Gale, 1987). The major concepts for an assessment and formulation in family therapy are listed by Dare (1985) as follows:

(i) seeing the family as having an overall structure;

(ii) understanding the symptom as having a potential function;

(iii) understanding the location of the family on the life cycle;

(iv) understanding the intergenerational structure of the family;

(v) making an overall formulation linking the preceding four features;

(vi) linking the formulation to appropriate interventions.

Typically, an assessment by a family therapist (see Lask, 1987) might concern itself with whether there is:

(i) too great a distance between members of the family, leading potentially to emotional isolation and physical deprivation;

(ii) excessive closeness between members of the family, leading potentially to overidentification and loss of individuality;

(iii) an inability to work through conflicts, solve problems, or make decisions;

(iv) an inability on the part of parents to form a coalition and to work together, with detrimental effects on the marriage and/or the children;

(v) an alliance across the generations, disrupting family life, as when a grandparent interferes with the mother's child-rearing decisions;

(vi) poor communication between members;

(vii) a failure to respond appropriately to each other's feelings.

Some of the ways in which a child may contribute (wittingly or unwittingly) to a family's inability to cope with conflict have been described by Lask (1987):

(i) *parent–child coalition*, where one parent attacks the other, using one of the children as an ally;

(ii) *triangulation*, where both parents attempt to induce a child to take *their* side;

(iii) *go-between*, where a child is used to transmit messages and feelings;

(iv) *whipping-boy*, where one parent, instead of making a direct attack on the other, uses their child as a whipping-boy;

(v) *child as weapon*, where one parent attacks the other using the child as a weapon;

(vi) *sibling transfer*, where the children agree to divert the parents' arguing.

There are family therapists who neglect to assess the influence of wider social systems (e.g., school, neighborhood, sociocultural network). The social context is played down as a source of influence. It is an article of faith that the outward and visible signs of the family's problems, as manifested to a group of observers/commentators behind a one-way screen, represent reliably what is going wrong. How representative of a family's repertoire the samples of interaction (sometimes distorted by observer effects) are in reality, is a moot point.

Bronfenbrenner (1979) recommends the assessment of the following systems when producing a formulation:

(i) *microsystems*, which are the daily settings of the client (e.g., home, school, work), the physical environments, and the people within these settings with whom the client interacts;

(ii) *mesosystems:* the links between microsystems (i.e., the name and quality of connections between the environments);

(iii) *exosystems:* the situation (e.g., mother working full time) which may impact on the client's life, but in which he or she is not directly involved;

(iv) *macrosystems:* the broad institutional patterns and value systems of the culture which affect the meso- and exosystems.

Whiting (1963) points out that the most significant actions taken by parents, significant in the sense of having the most impact on children, have to do with their assignment of children to various niches or settings in a society, from crèches and nurseries/kindergartens to private schools, apprenticeships, helping sell produce in the market, or tending animals. Each of these settings has flow-on effects upon the people children encounter, their opportunities for play with peers, and their opportunities to acquire informal cognitive skills. These many and varied influences give the child his or her unique quality.

The individual client is also conceptualized in systemic terms. For example, Hepworth and Larsen (1990) make a formulation on the basis of describing (say) the child as a system composed of six intrapersonal dimensions:

(i) biophysical functioning (e.g., physical attributes, physical health, use and abuse of drugs and alcohol);

(ii) cognitive and perceptual functioning (e.g., cognitive level and flexibility, self-concept, judgment);

(iii) emotional functioning (e.g., emotional control, depression, anxiety);

(iv) behavioral functioning (e.g., deficits, excesses, patterns of concern);

(v) motivation (e.g., precipitating events);

(vi) culturally determined patterns (e.g., norms, values).

What we now have is an assessment process which may be focused on an individual (e.g., child), a group (e.g., family) or an organization (e.g., school). The first is sometimes neglected in family therapy formulations.

The family is thought of as dynamic in the sense that it is subject to continuous change. Like individuals, families are believed to pass through developmental life-cycle stages. Each life-cycle stage is believed to have its own accompanying set of tasks to be accomplished if families are to make successful transitions from one stage to the next (Carter & McGoldrick, 1988). A concept like that of life stages highlights a problem for practitioners assessing families. How do they adopt a standard by which to evaluate functional ("healthy") as opposed to dysfunctional ("unhealthy") patterns of family organization, transitions, boundaries, homeostatic (equilibrium-seeking) strategies, rules, roles, decision-making processes, communications, or any of the other attributes family therapists believe to be significant? Obviously, there are diverse cultural "norms" or values in these matters.

What is not always clear in clinical formulations which highlight the types of causal influence listed by Lask (above) is the precise mechanism whereby family patterns relate functionally to the day-to-day specificities (i.e., with regard to persons, places, times, or situations) of the referred problem. The majority of nonbehavioral family therapy processes are formulated in somewhat global terms and pitched at a high level of abstraction. It becomes very difficult to define operationally the key independent treatment variables at this level of strategy generality (de Kemp, 1995). At the dependent variable end of the therapeutic equation, emphasis can be placed on symptom reduction/removal alone (called first-order change), or a more systemic level of family transformation (second-order change). Second-order change is empirically and conceptually difficult to identify and quantify.

The primary goals of family therapists, as defined by family therapists from several disciplines, tend to be divergent. Furthermore, there is little consensus about which factors constitute evidence of an efficacious outcome. A survey (*inter alia*) of family therapists' primary goals for therapy (Group for the Advancement of Psychiatry, 1970) elicited the following objectives expressed as percentages with regard to all families:

(i) improved communication (86%);

(ii) improved autonomy and individuation (56%);

(iii) improved empathy (56%);

(iv) more flexible leadership (34%);

(v) improved role agreement (32%);

(vi) reduced conflict (23%);

(vii) individual symptomatic improvement (23%);

(viii) improved individual task performance (12%).

Practitioners are not always clear about whether they are concerned with symptom reduction, family restructuring, or both.

Critical surveys (e.g., Herbert, 1987a; Kaslow, 1980; Reimers & Treacher, 1995) suggest that pragmatic, structured family therapies (i.e., those concerned principally with behavioral change) have produced the most convincing evidence of effective therapeutic outcome for the psychosocial problems of children. A particular criticism of the family therapy field is their antiempirical stance and consequent rejection of basic research (e.g., Watzlawick, Weakland, & Fisch, 1974).

5.02.4.5.1 Behavioral family therapy

The work of Patterson in Oregon was part of, and the inspiration for, a rapid growth in what might be called "behavioral family therapy" (see Alexander & Parsons, 1982; Griest & Wells, 1983; Herbert, 1994b; Patterson, 1982). This approach—sometimes also referred to as "systemic behavioral therapy"—is in large part concerned with the assessment of naturally occurring environmental influences, specifically those occurring within the family between parents, siblings, and child, in order to modify deviant behavior and teach new skills and behavior repertoires. It is an elaboration of learning-theory-based behavior therapy, and finds much of its intellectual sustenance in social learning theory. The basic level of formulation remains the functional analysis to which is turned to; it illustrates neatly the scientist-practitioner way of working, the approach of the applied psychologist.

5.02.4.6 The Behavioral Model—Functional Analysis

Haynes and O'Brien(1990) define functional analysis as: "the identification of important, controllable, causal, functional relationships applicable to a specified set of target behaviors for an individual client" (p. 654). In the behavioral canon, the formulation is directed towards the precise identification of the antecedent, outcome, and symbolic conditions which control the problem behavior. Behavior theorists often refer to their assessment—as a simple mnemonic for clients—in ABC terms (see Figure 3).

From a behavioral perspective, a child who indulges in frequent acts of defiance and outbursts of verbal abuse would be observed in order to determine the specific circumstances and conditions in which the unacceptable behaviors occur. Such conditions may involve antecedent organismic (O) and/or environmental stimulus events (A) which precipitate or set the scene as discriminative stimuli for the outbursts and the consequent events (C). The B term in the ABC analysis can stand for the behavior(s) being studied and the beliefs (attributions, perceptions, interpretations) of the child/parents about what is happening, why it is happening, and what the outcomes are likely to be.

The formulation involving an ABC linear analysis is, of necessity (given the complexity of behavior), elaborated into a recursive sequence such that Cs become As that generate new Cs, and so on. Learning occurs within a social nexus; rewards, punishments, and other events are mediated by human agents within attachment and social systems and are not simply the impersonal consequences of behavior. Children do not simply respond to stimuli; they interpret them. They are relating to, interacting with, and

(possible precipitants)

Carlton is asked to do something or to stop it.

2. *Behavior*
(a) Non-compliance. He takes no notice; if his mother insists, he resorts to verbal abuse.

(b) Verbal abuse. He makes rude comments, criticizes, occasionally swears, and shouts.

3. *Consequences*
(possible reinforcers)
(a) Mother shouts at him, scolds him, or discusses at length with him what he has done.

(b) She begs him.

(c) Usually he gets his own way.

Specifity of Carlton's responses

Persons: He is rude and disobedient mainly with his mother; occasionally to his father; never with his grandmother.

Places: Anywhere (but notably when visiting, or at a supermarket).

Times: Meals in particular — at the beginning, usually, of the family meal.

Situations: Mainly when asked to do something or when challenged over being late for meals or for bad manners. Particularly when questioned about, or criticized for, not eating properly, getting up and leaving the table.

Figure 3 The ABC of behavoir.

learning from people who have meaning and value for them.

Bandura (1977) suggests that stimuli influence the likelihood of particular behaviors through their predictive function, not because they are automatically linked to responses by occurring together; contingent experiences create expectations rather than stimulus–response connections. Not surprisingly, behavioral work based on this premise is increasingly systemic, dealing with caregivers and nominated child "patients" in their own right as individuals, and analyzing their relationships to each other (as dyadic attachment subsystems). Also studied are their communications, interactions, boundaries, and perceptions of one another within a holistic and dynamic family system.

5.02.4.6.1 Behavioral formulations

In identifying controlling variables, the contemporary causes of problem behavior may exist in the client's environment or in his or her own thoughts, feelings, or bodily processes (organismic variables), and they may exert their influence as proximal (current) influences which are direct in their effects and close in time to the actions they influence. They are functionally related to behavior and can thus be tested in therapy—as hypotheses about causation—using single-case experimental designs. The formulation is directed toward the precise identification of the antecedent, outcome, and symbolic conditions that control the problematic behavior or beliefs (see Figure 4).

A distinction is made between the direct and vicarious learning experiences that contribute to the acquisition of problematic behavior and those contemporary influences which determine whether the client will perform the behavior he or she has acquired. For example, in the conduct disorders, some antisocial action which has been acquired by imitation or modelling may not be performed, either because appropriate instigating conditions do not occur or because its consequences are likely to be unrewarding or unpleasant. Maladaptive actions that are reinforced in terms of favorable consequences tend to be repeated. The reinforcement which strengthens an adolescent's disruptive behaviour—to take an increasingly typical example from the contemporary classroom—may be in terms of direct external reinforcement, vicarious or observed reinforcement, or self-reinforcement.

5.02.4.6.2 Distal consequences (Figure 4)

While it is true to say that clinicians delineate certain "symptoms" as pathognomonic of particular psychiatric disorders, the fact is that in the area of disorders of childhood it is mainly social rather than medical criteria of what is problematic that are dealt with. It is important to look not only at the immediate consequences of a client's behavior, but also at the longer-term implications (distal outcomes). What are the likely consequences of nonintervention in the problem for the person and his family? Problem behaviors are usually so called because they have a variety of unfavorable short-term and long-term outcomes. They are therefore referred to as maladaptive actions or dysfunctional thoughts and feelings; they are inappropriate in terms of several criteria which are assessed by the therapist.

Ultimately, the professional judgment of a client's behavioral/psychosocial/mental status is made in individual terms, taking into account his or her particular circumstances. It involves an estimate of the consequences that flow from the client's specific thoughts, feelings, and behaviors and general approach to life, with particular reference to their personal and emotional well-being, their ability to form and maintain social relationships, their ability to work effectively and (in the case of children) learn academically, and their accessibility to socialization (Figure 4, category 7). All are subject to disruption in emotional and behavioral disorders, and are gravely affected in the conduct disorders of childhood and adolescence (Herbert, 1987a). Other factors to be considered are youngsters' self-esteem and competence.

Social psychology can contribute to the overall assessment (Durkin, 1995). Take, for example, the socially isolated child: immature, self-centered children are not always able to manage the give-and-take of friendship. Exchange theory gives us pointers to why this should be so; it provides one method of evaluating friendships. Those theorists who employ "exchange theory" in analyzing aspects of social behavior and friendship view social interactions as a social exchange somewhat analogous to economic exchange. People are influenced (consciously and unconsciously) by the ratio of "rewards" to "costs" incurred in the interaction.

In the assessment of the implications for social relationships, it might be useful to draw up a balance sheet. On the debit side, the term "cost" is applied to deterrents that may be incurred in contacts with another person—such as hostility, anxiety, embarrassment, and the like. For attraction to a potential friend to occur the reward–cost outcome must be above the "comparison level," a standard against which satisfaction is judged.

Figure 4 A conceptual framework for an assessment of behavior problems. This figure represents the author's conceptual map of the essential data to be obtained for a clinical formulation. It takes account of the client, significant others (e.g., interactions), behaviors and beliefs, current and historical events. It also provides diagnostic criteria by examining the longer-term implications of these behaviors and beliefs.

Organismic variables include individual differences produced by age, sex, genetic constitution, physiology, and by cognitive representations (schema, attributions, etc.) based on past learning (Figure 4, category 4). Behavior therapists tend to adopt a transactional position—the view that behavior results from a (still poorly understood) interaction of the current situation and individual differences (biological and psychosocial).

5.02.4.6.3 The formal assessment

Assessment in the behavioral mode involves a recursive process both in repeatedly testing and in revising the model of the person's behavior. It is also repeatedly used to monitor changes in the person's behavior across time and settings. Repeated evaluation is also essential to evaluate and modify treatment. The assessment procedure is idiographic and tailored very carefully to the person's own unique configuration of strengths and weaknesses. Behavior therapists insist on carefully monitored pretreatment assessments. They believe that the client—which may include adults (e.g., parents) as well as children—is best described and understood by determining what he or she thinks, feels, and does in particular life situations. The goal is eventually to help the clients to control their own behavior and achieve self-selected goals. It is crucial in behavioral assessment and treatment to reformulate these complaints and goals in operational terms, that is, in overt terms of what the client says and does, and in a manner that lends itself to quantifying the problem (Ollendick & Hersen, 1984).

Wilson and Evans (1983) studied the reliability of target behavior selection in behavioral assessment by asking 188 members of the Association for Advancement of Behavior Therapy to assess three written case descriptions of (i) fearfulness, (ii) conduct disorders, and (iii) social withdrawal in children. Subjects were posed four open-ended questions: (i) whether treatment was warranted; (ii) to describe the child's major difficulty; (iii) state treatment goals; and (iv) specify and rank order treatment targets. Granted that the means of assessment is somewhat artificial there was nevertheless a surprisingly low agreement (38%) between clinicians in selecting a first-priority behavior for treatment. There was considerable variability in selecting behaviors for intervention and, perhaps surprisingly, a substantial (22%) tendency to introduce psychodynamic and intrapsychic terminology such as "internalized hostility," "poor self-concept," and "insecure child." Only approximately 20% of responses referred to specific target behaviors. Psychodynamic explanations were more likely in complex problems. This study is a matter of concern for advocates of functional analysis if its results are cross-validated. It indicates poor agreement between raters on the apparently simple task of identifying target behaviors.

Two questions regarding the validity of functional analysis are especially important: "What constitutes an adequate functional analysis?" and "When are the clinician's judgments valid during functional analysis?" Oliver and Head (1993, p. 14) reviewed published criteria for an adequate functional analysis and suggest that three criteria must be met: "that behavior (B) is considered in terms of the influence of events preceding the behavior, or its antecedents (A), and the events consequent (C) upon it...That the influences of antecedents and consequences should be empirically demonstrated...That all necessary and sufficient conditions for a behavior to occur should be considered."

Contemporary behavior analysts use and integrate many different assessment methods, including interviews with the client and third parties, psychometric assessments, idiographic self-reports, psychophysiological measures, and mini-experiments (Dougher, 1994; Sturmey, 1996). The purpose is to generate and evaluate hypotheses concerning the clinical problem. Information is collected which requires careful interpretation. At times this may be a highly inferential process. Although the functions of target behaviors may be readily apparent in some situations, this is not always the case.

Barrios (1988) notes that assessment, including behavioral assessments, may serve many different purposes. Behavioral assessment has been used in order to assist in diagnosis to evaluate treatment efficacy, to evaluate the most appropriate form of intervention for an individual client; also to assess whether clients are capable of change (e.g., in their parenting practices (Herbert, 1991b)).

5.02.4.7 Developmental-behavioral Formulations

"Development" is typically defined as a progressive series of orderly, coherent changes leading to the goal of maturity. This may be the grand design, but as many long-suffering parents and teachers know to their cost, children's progress through life is often disorderly and incoherent, and the changes (when change is not being resisted) are not always in the direction of maturity. Developmental frameworks for assessing individuals and families emerged from research and theory relating to their progress through life-cycle stages, and the therapeutic strategies they generate (e.g., Carter & McGoldrick, 1988). Several theorists (e.g. Achenbach, 1974, 1982; Cicchetti, 1984a, 1984b; Herbert, 1974) have urged the necessity for underpinning the study of child psychopathology with principles and findings from developmental psychology—an approach which has been referred to as the "developmental psychopathology movement" (Gelfand, Jensen, & Drew, 1988). This developmental framework has been applied to clinical practice in the form of a broad-based, interdisciplinary knowledge-base, incorporating works as diverse as that of ethologists, developmental neurologists, cognitive anthropologists, cognitive-development theorists, and social-learning theorists.

5.02.4.7.1 A developmental knowledge base

The difficulty for the clinician formulating his/her assessment within a developmental context is that there is no agreed, conceptually coherent theory of normal child development as a touchstone for understanding and assessing clinical abnormality, nor any single explanation of the processes of normal growth and development. Developmental theories range from the psychoanalytic (e.g., Freud's stages of psychosexual development), the ethological (e.g., Bowlby's attachment theory), behavioral (e.g., Bandura's social-learning theory) to the structural-developmental (e.g., Kohlberg's theory of moral development). Each of these theoretical perspectives provides a particular methodology and conceptual framework for viewing the specifics of developmental processes. Conceptions of individual characteristics also vary from those postulating stability to those assuming constant change. For example, trait theorists investigate nomothetically, relatively fixed relationships between characteristics (e.g., temperament, intelligence) across various ages, while those favoring an idiographic approach examine the individual's unique and dynamically changing organization of personality attributes.

A contemporary assessment framework leading to a formulation and treatment plan for childhood psychological disorders (see Herbert, 1987b; Ollendick & King, 1991) requires measures of behavioral, cognitive, and physiological responding as well as, notably, a determination of the developmental, social, and cultural context within which the problem occurs. The strategy is to begin with a broad-based assessment of the child and his or her environment (e.g., family, school, peers) and then to obtain information regarding specific stimulus features, response modes, antecedents, and consequences, severity, duration, and pervasiveness of the particular problems. The assessment utilizes a multimethod, problem-solving approach to obtain as complete a picture of the child and the family as is possible, one that generates in logical fashion, a treatment plan. The design of such treatment plans requires a multidimensional model in order to accommodate conceptually the different social contexts (home, school, and neighborhood) and the various levels of intervention that characterize child behavior therapy.

There are several key developmental questions to ask in formulating whether a problem merits serious concern:

(i) Do the child's problems interfere with the forward momentum and course of normal development?

(ii) Are they causing him/her to "regress," or slowing him/her down?

(iii) Do they represent a "cul-de-sac," taking him/her in the direction of a self-defeating lifestyle?

(iv) Is the child's adaptive behavior appropriate to his/her age, intelligence, and social situation?

(v) Is the environment making reasonable demands of the child?

(vi) Is the environment satisfying the crucial needs of the child, that is, the needs that are vital at his/her particular stage of development?

The family (or some other agent of socialization) may be dysfunctional. Thus, if the child's behavior is abnormal (unusual), troublesome, and self-defeating—and the answers to the last two questions are "No"—then you are still faced with a problem. However, it is more of a "problem situation" than an intrinsic disorder, or, more accurately, a systemic, interactional problem.

For Cicchetti and his colleagues (Cicchetti, Toth, & Bush, 1983) abnormal patterns of behavioral adaptation—as represented by clinical problems such as hyperactivity and failure-to-thrive—are most fruitfully construed and formulated as a series of stage—and age-related "tasks." The issue of "competence" is common to all of them and, as the child gets older, his or her self-esteem. If the child fails to develop skills and social competence, he or she is likely to suffer a sense of inadequacy which has spiralling ramifications. There is evidence, not only of the power of parents to facilitate the child's mastery of developmental tasks or hinder him or her, but to do this unwittingly (Cicchetti, Toth, & Bush, 1983). These matters become important themes in the final formulation.

The evaluation of normality and abnormality within a developmental framework requires a familiarity with general principles of development with particular reference to personality and behavior. It necessitates a comprehensive knowledge of children, how they think and talk, their skills and limitations at various ages, their typical repertoires of behavior, and the life-tasks and crises that they confront. Such a normative or comparative approach needs to be complemented by an idiographic assessment which takes into account biographical and social-contextual influences (Whiting, 1963).

The value of a developmental framework for clinical work does not cease after adolescence. We do not stop developing as adults. It is shortsighted to try to understand, say, an adolescent's misdemeanors without considering the preoccupations and attitudes characteristic of his or her parents' stage of life.

5.02.4.8 Social-learning Model—Cognitive-behavioral Approach

Behavior does not occur in a social vacum, nor is its acquisition a passive process. Human beings are problem solvers and active explorers of their world. Cognitive-behavior therapists (e.g., Hollon & Beck, 1994) subscribe to a model of human behavior and cognition which goes beyond the earlier epistemological position of radical behaviorists and focuses on the active processing of expectations, hypotheses, and theories. These have been added to that other "ghost in the machine"—the self—with which most behavior therapists now happily (and others, uneasily) cohabit.

An important feature of the social learning model, within which cognitive-behavior therapy finds much of its theoretical rationale, is the acknowledgment of this active element in learning and the part played by *understanding*. Not all of a child's learning (e.g., to ride a bike) involves understanding, but much learning involves knowing rather than simply doing. Stimuli, notably social stimuli, have meaning for the child, who acquires knowledge of social situations which is used in adapting to them. The failure to comprehend these meanings—as seen, for example, in the child with a Semantic-Pragmatic Disorder—has a devastating effect.

The cognitive-behavior therapy approach does not lend itself to any one simple definition (see Fishman, Rodgers, & Franks, 1988; Guidano & Liotti, 1983). Its focus, however, on goal setting and self-directive behavior by the client, and on divergent thinking as a means to inventive solutions to life's problems, is congruent with the philosophy of much contemporary casework with children and their families. Therapists assess, as primary data, children's problematic behavior, but also the phenomenology of their problems: their verbal reports of internal representations of events, experiences, and opinions, such as attitudes towards self, parents, and school. These attitudes, like theories, have, *inter alia*, a knowledge function. They provide a frame of reference within which individuals make interpretations of their world, creating a model—a figurative set of "goggles"—through which they construe and make sense of people and life-events. This personal construct system (Kelly, 1955) is accessible to investigation by means of the Kelly Repertory Grid.

The constructs of parents, some developed in the bosom of their family of origin, others elaborated with more recent experiences of parenting, give meanings to their offspring's behavior and can facilitate mutually-satisfactory interactions. Sadly, some constructs, if distorted by ignorance, misunderstandings, or paranoia, can mislead parents into self-defeating confrontations with their children.

There is a wide range of cognitive-behavioral methods; they share a common assumption that children (and, indeed, their parents) can be helped to eliminate dysfunctional attitudes and behaviors and to learn more adaptive strategies and skills (e.g., self-control, effective communication, negotiation), by reinforcing prosocial and socially sensitive behavior, challenging irrational beliefs and faulty logic, and by self-instruction and positive self-statements as well as the more traditional behavioral change techniques (Herbert, 1987b, 1989, 1993, 1997b; Kendall & Braswell, 1985).

5.02.4.9 Integrative Models

Given that there is no grand, general psychological theory of human behavior on offer in academic psychology departments, but rather a number of poorly integrated middle-range theories (e.g., learning theory, cognitive science, etc.), it should not be surprising that clinical psychologists find few convincing overarching theories or integrative models to make sense of psychopathology in childhood or adulthood.

The Kendall and Lochman (1994, p. 844) description of the cognitive-behavioral therapies is in terms that suggest there is a broader convergence of concepts in their rationale than in most of the other approaches. They state that:

> ...they integrate cognitive, behavioral, affective, social and contextual strategies for change. The cognitive-behavioral model includes the relationships of cognition and behavior to the affective state of the organism and the functioning of the organism in the larger social context.

A rationale for many practitioners is that all therapies contain an element of *learning*, something about which psychologists have considerable knowledge and experience of workable applications. Goldstein, Heller, and Sechrest (1966, p. 63) propose the following definition of psychotherapy:

> Whatever else it is, psychotherapy must be considered a learning enterprise. We need not specify too narrowly just what is to be learned in psychotherapy; it may be specific behaviors or a whole new outlook on life, but it cannot be denied that the intended outcome of psychotherapy is a change in an individual that can only be termed a manifestation of learning.

In the author's opinion, what gives cognitive-behavioral therapy its present ethos of an informed rather than ragbag eclectism, is its deep roots in empirical psychology, and a track record of encouragingly successful outcomes in a wide range of childhood behavior problems (Herbert, 1997a, 1997b; Kendall & Braswell, 1985; Kendall & Lochman, 1994).

5.02.5 THE CLINICAL FORMULATION—PRACTICE ISSUES

Rigorous assessment is the *sine qua non* of effective intervention. The formulation, which bridges these activities, depends upon the clinician's practice wisdom and skill in "mining" for the data with which it is constructed. The different stages of the ASPIRE process leading towards a formulation (described at the beginning of this chapter), involve a sometimes daunting array of practical choices, decisions, actions, and caveats. Not infrequently, incoming data—sometimes as far forward in client contact time as the intervention—demands a reformulation and possibly a "rethink" of the therapeutic program.

As any choice of key issues to discuss for their practice implications is likely to seems somewhat arbitary a few areas found to be important for clinical practice have been selected (see Tables 1 and 2).

5.02.6 CONDUCTING A FORMULATION

5.02.6.1 The Intake Interviews—Preparation

The interview is an essential method for gaining access to parents' and children's problems. It sounds deceptively simple and straightforward but requires careful preparation. The following questions illustrate some of the issues:

(i) What do I wish to find out (what are my objectives in this interview?)

(ii) Who do I need to speak to in order to fulfill my objectives? (All the family members; parents only; the child alone; his/her brothers and sisters?)

(iii) Do I invite them to meet me as a full family group? Do I speak to the mother first? Both parents together? Should the child be present initially?

(iv) How do I begin the interview?

(v) How do I introduce myself?

(vi) How do I let them know what to expect?

(vii) How do I best express some quite complex and potentially threatening ideas?

(viii) How do I reassure them about confidentiality?

(ix) What is the best way of eliciting reliable and relevant information?

(x) How do I deal with their tendency to digress or to set an agenda which avoids key issues?

(xi) Indeed, what *is* relevant (salient) information?

(xii) How do I terminate the interview, without leaving clients feeling "up in the air" or threatened?

5.02.6.2 Engaging the Clients

There is an important general consideration: the perspective, "style," or model of help to be adopted. In the expert model the professionals view themselves as very much in charge because of their monopoly (or near-monopoly) of expertise, responsibility, and, therefore, decision-making. The client is relatively passive as a recipient of advice, "prescriptions" (about health or how to behave), or possibly therapy of one kind or another. At the other extreme, clients (say parents) are viewed very much as consumers of the professionals' services, with the right to select what *they* believe is most appropriate to their needs. Decision-making is ultimately in the parents' control, with professionals acting as consultants, negotiation and discussion playing a large part in the client–practitioner relationship. The formulation is very much a self-directed, demystified process.

In between, lies the collaborative or partnership model. Here the professionals perceive themselves as having expertise but sharing it and imparting it to parents and other non- or paraprofessionals so that *they* facilitate much of the training/therapy of the child.

Cunningham and Davis (1985), in the context of work with mentally handicapped clients, devised a list of questions for estimating where one stands on the expert–consumer continuum vis-à-vis clients:

(i) Have I met the family?

(ii) Do I consider the child in the context of his/her family?

(iii) Do I have regular, two-way communication with the family?

(iv) Do I respect and value the child as a person?

(v) Do I respect and value the family?

(vi) Do I feel the family has strengths to help the child?

(vii) Have I identified the parents' abilities and resources?

(viii) Do I always act as honestly as possible?

(ix) Do I give them choices about what to do?

(x) Do I listen to them?

(xi) Have I identified their aims?

(xii) Do I negotiate with them?

(xiii) Do I adjust according to the joint conclusions?

(xiv) Do I assume they have some responsibility for what I do for their child?

(xv) Do I assume I have to earn their respect?

(xvi) Do I make the assumption that we might disagree about what is important?

(xvii) Do I believe they can change?

(xviii) Have I tried to identify the parents' perceptions of their child?

(A high proportion of "yes" responses suggests the generalized use of a consumer model; many "no" responses indicates an expert model).

5.02.6.3 The First Contact

The clinician conducts a guided conversation in which they ask questions and listen empathetically (with the "third ear" as it has been called) to the answers and to spontaneous comments. A collaborative style comes into effect from the very first encounter if this is the approach of choice. The practitioner, after explaining their role and what lies ahead for the client(s), attempts to engage willingness to cooperate and possibly change, by entering the client's concerns, experience, and feelings. The construction of a family tree (genogram) is a useful means—especially with children—of establishing rapport and getting to know who significant members of the family and friends are (Herbert, 1991b).

Parents are invited to explain their coping and disciplinary strategies, as well as their theories regarding possible causes of the child's problems which they have had the opportunity to describe. Ideally, they come to feel that the clinician is making a genuine effort to understand their internal reality. Other matters for discussion are the child's assets, and the parents', and, if present, the child's hopes and goals for therapy (see Herbert, 1987a, 1987b; Webster-Stratton & Herbert, 1994, for detailed accounts).

5.02.6.4 The "What?" Question

A failure to define the client's problem in precise terms, or to bring the circumstances in which it occurs into sharp focus, leads to the premature formulation of cause–effect relationships. To discuss causal factors before the "to-be-explained" phenomenon is adequately specified and measured is a reversal of scientific problem-solving.

Table 1 Beginning an assessment.

Initial screening	*Phase 1*
Step 1	Explain how you intend to work. Foster a good working relationship
Step 2	Obtain a general statement of the problem(s)
Step 3	Specify the problem(s) more precisely
Step 4	Elicit the desired outcome(s).
Step 5	Construct a problem profile (Herbert, 1987b)
Step 6	Introduce the idea of behavior sequences by looking at your client(s) typical day(s)
Step 7	Establish problem priorities
Further assessment	*Phase II*
Step 8	Work out a family life map (Herbert, 1988)
Step 9	Make an estimate of your client's assets
Step 10	Ask your adult clients about their goals (e.g., for their children). Ask the child about his or her wishes and requirements
	Phase III
	Collect more detailed "baseline" data. Give clients homework tasks, for example, keeping diaries, frequency charts, etc ...

Table 2 From planning to implementation.

Planning	*Phase 1*
Step 1	Consider informal and/or direct solutions
Step 2	Accentuate the positive
Step 3	Consider the wishes of those around the client
Step 4a	Begin with problems where success is likely
Step 4b	Select relevant areas of change
Step 5	Choose your intervention
Step 6	Monitor your client's progress
Implementation	*Phase II*
Step 7	Implement the intervention
Step 8	Review your intervention
Step 9	Gradually fade out the program
Follow-up	*Phase III*
Step 10	Conduct a follow-up exercise

This is not the place to consider the many aids to description and measurement for formulation purposes, that are available. (Useful guides to the psychometric and evaluative literature are available in Barkley, 1990, 1994; Berger, 1996; Ollendick & Hersen, 1984; Ollendick & King, 1991; Scott, 1996; Webster-Stratton & Herbert, 1994).

There are several "what" questions which, with others, generate precise hypotheses to explain the child's difficulties:

(i) What is the child doing and saying that is problematic?

(ii) Under what conditions are these behaviors emitted?

(iii) What tasks/problems is the child confronting in his/her life-situations?

(iv) What pro-social behaviors does the child emit?

(v) Under what conditions do these behaviors occur?

(vi) What situations are being avoided?

(vii) What are the implications for the child (and significant others) if s/he does not change?

(viii) What actions need to be encouraged and shaped up?

The preliminary information about the referral comes usually from parents. They tend to report their children's problems in terms of rather vague, global labels such as "aggressiveness," "tantrums," "defiance," or "rebelliousness." It is vital to encourage them to give descriptive examples of the problem, in other words to define what they mean in specific and observable terms. There follow two examples of a parent's complaint. The first is uninformative; the second provides a firm foundation for further assessment.

(i) Peter was playing with his cars when I asked him to get ready for school. Peter took no notice. I snatched away his toys and there was a scene. As a result, Peter had one of his tantrums and gave me a lot of abuse.

(ii) Peter was playing with his cars. I told him it was already 7.30 and time to get washed, dressed, and ready to leave for school. Peter did not answer or make a move. I told him the time again and repeated my instructions. Peter asked for a few minutes play. I said he was already late and told him to put the cars away. He now said "No!" just like that. I snatched his cars away. He lay down, screamed, and kicked his legs on the floor for a few minutes until I smacked him. He then went to change, muttering that he hated me and would leave home. I took no notice. His father took no interest in what went on; he ignored the entire thing.

After an initial report from parents (or teachers), the clinician needs to observe the child. It is important to confirm the parents' observations and especially those based on hearsay, for example, what she has heard about her child's behavior at school. A major source of error in the assessment and treatment of children in clinics or residential settings is the tendency to ascribe to the child properties which overemphasize the generality and invariance of personality traits and problem behavior. Such reification undermines effective formulating.

As an example, the problem could be a boy who bullies other children. The tendency is to make an entity of the bullying. It is done by describing the problem in the form of a noun or adjective ("there is a lot of violence in him"; "he is an aggressive boy"). The youngster is assessed in terms of what he is or has rather than in terms of what he does in particular situations. In the next stage the child is quite likely to be inferred to have "a need for aggression." From this point on, the distinction between what is observed and what is inferred, what is direct evidence and what is hearsay interpretation tends to become blurred. For all the popularity of trait theories, practitioners, as we have seen, make little use in therapy of the diagnostic information from personality typologies.

Behaviorally oriented psychologists tend to view behaviors with, say, aggressive or anxiety attributes as instances or samples of response classes rather than as the outward and visible signs of internal or underlying dispositions. They tend to avoid trait labels. Diverse attributes would be considered to be members of the same response class because it could be shown that such attributes enter into the same functional relationships with antecedent, concurrent, and consequent stimulus conditions, rather than because they coexist or covary in a group of persons.

5.02.6.5 Unpacking the Problem

In the case of complex problems it is helpful to have (or to construct) a conceptual framework—a guide to the factors that require investigation. Figure 5 presents an example of how, with a problem like school refusal, the clinician can unpack or unravel the processes underlying the problematic situation into their constituent elements, as an aid to the assessment and formulation. Thus with the school refusal problem the clinician might ask: "What does a young person have to do in order to go to school (successfully), remain at school, and then return home at the appropriate time?" "What incentives ('push–pull') or deterrent influences are operating in this child's situation?" The flow chart (Figure 5) illustrates the "push" and "pull" factors which function to impel or attract children to school, and hold them there, and the stages at which things can go wrong.

5.02.6.6 Communication

Young children tend to be talkative but may be limited in their ability to reflect insightfully about their experiences; adolescents are often introspective (reflective) but have a way of becoming monosyllabic when asked personal questions. This poses a problem for the would-be interviewer.

Children are not always very good at expressing their fears, frustrations, or uncertainties. They cannot always tell their parents, let alone a comparative stranger, how they feel, but they have a language that adults can learn to translate—the language of behavior and fantasy. What they do (in a direct sense in everyday life) and say (indirectly through play or storytelling) can be most revealing. The advantage of using projective techniques (which include play, puppets, dramatic creations, completing stories or sentences) for assessment, is that they involve relatively unstructured tasks that permit an almost unlimited variety of responses. The client has to fall back on his or her own resources rather than stereotyped, socially desirable answers. The techniques (as psychometric instruments) do have their critics, but are invaluable if used cautiously as aids to communicating with children (Babiker & Herbert, 1996).

Where the child is too loyal, too frightened or ashamed, or too inarticulate to speak about feelings (or painful events in the family) it may be possible to express these emotions in play, drawing, drama (with puppets or miniatures), or stories. They are undoubtedly an invaluable adjunct to work with children and involve the empathic imagination and creativity referred to at the beginning of this chapter (see Herbert, 1988).

5.02.6.7 The "Which?" Question

An issue which arises early in a clinical assessment involves prioritizing problems. Clinicians with mandatory obligations have their own guidelines to follow. The practitioner's and parents' hierarchy of tasks might be influenced by the following considerations with regard to the problem(s):

(i) their annoyance value;

(ii) their actual/potential dangerousness;

(iii) their interference with the life of the family or its individual members;

(iv) their accessibility to change (improvement) and an intervention;

(v) their frequency, intensity, and magnitude;

(vi) their disabling implications;

(vii) the "costs" of change in terms of resources (time, money, etc.) and other people's well-being;

(viii) the ethical acceptability of the desired outcome;

(ix) the availability of the necessary helping skills or resources.

5.02.7 THE FORMULATION

The formal or main phase of assessment can be said to be over when the clinician has a reasonably clear picture of the clients' difficulties, strengths, history, social setting, and background. They should have a reasonably clear picture of why the problems developed and how they "look" against a framework of normal development. Relevant intrinsic attributes of the child have been assessed. The problem is

Has to wake up on time → Get bathed, dressed, breakfasted → Leave the house on time → Make a journey → Enter the school gates → Go to assembly → Stay in the school → Go home at appropriate time →

(1) Does he wake on time? If not, why not?
(2) Does he get enough sleep? If not, why not (going to bed late; lying in bed unable to sleep because of morbid preoccupations, tense, depressed?)

(3) Anyone to structure his day at home, e.g. supervise his getting ready (“push”)?
(4) Is he sick/anxious/panicky?
(5) Any reason he needs to be at home (care for a sick member of the family, parents keep him at home to look after siblings, etc.)?
(6) Is he afraid to leave home because concerned about his mother’s health, afraid of an accident befalling her (preoccupation with death, separation anxiety)?
(7) Is he depressed, overwhelmed by apathy, helplessness, inertia?

(8) Is he teased/bullied on the way to, or at school?
(9) Claustrophobia/clothing (adequate for school?)/homework
(10) Is there anything to keep him at school (interests, friends, teacher)?
(11) Deviant models (peer group) for truanting
(12) Other “pull” factors absent? (Is he under-achieving grossly at school, bored?)
(13) Does anyone really know him or take an interest in him at school?

Figure 5 “Push–pull” influences in a child’s school attendance.

formulated usually in systemic terms, that is to say as it impinges on a family or school system rather than on an individual alone.

5.02.7.1 The “Why?” Question

The formulation provides a summary of the salient information collected; it is “formulated” in the sense that the practitioner puts forward an “explanatory story” (hopefully, a valid one) to impose meaning on the data collected. The formulation consists of a series of hypotheses which are statements about how the problem arose, when and where it occurs, and why it is maintained.

A particular skill is one of editing. It involves the identification of the important influences and controlling variables—among, potentially, so many—in order to plan an effective intervention. The principle of parsimony is helpful here; one invokes those causal factors that are sufficient to facilitate such an intervention. There is a balance to be struck between the wastefulness and risks of overinclusiveness (that is to say excessive complexity), on the one hand, and simplistic theorizing on the other.

Bromley (1986) describes the required steps for explication of the individual case.

(i) State clearly the problems and issues.

(ii) Collect background information as a context for understanding (i).

(iii) Put forward *prima facie* explanations (conjectures/hypotheses) and solutions (program formulation) with regard to the client’s personality and predicament—on the basis of information available at the time, and on the basis of the principle of parsimony. Examine the simple and obvious answers first. They may, of course, have to be rejected if they don’t stand up to critical examination. This guides (iv).

(iv) Search for further/additional evidence. New hypotheses/explanations will have to be formulated and examined.

(v) Search again and admit for consideration, sufficient evidence to eliminate as many of the suggested explanations (hypotheses) as possible; the hope is that one of them will be so close to reality as to account for all the evidence and be contradicted by none of it. The evidence may be direct or indirect; but it is vital that it should be admissable, relevant, and obtained from competent and credible sources.

(vi) Enquire critically into the sources of evidence, as well as the evidence itself. Bromley (1986) makes the point that in the case of personal testimony, this is analogous to cross-examinations in a court of law; otherwise it amounts to checking the consistency and accuracy of all items of evidence.

(vii) Examine carefully the internal logic, coherence, and external validity of the entire network of associations and hypotheses formulated to explain the client’s predicament and proposals to solve the problems.

(viii) Select the “most likely” interpretation, provided it is compatible with the evidence (some lines of argument will be obviously inadequate whereas others will be possible or even convincing).

(ix) Work out the implications of your explanations for intervention/treatment or some other action (or, indeed, inaction).

Always ask yourself about the implications (e.g., the risks involved) of making Type I as opposed to Type II errors in your assessment. Is it more damaging to your client if you risk Type I errors (i.e., asserting relationships falsely) than if you risk Type II errors, which deny relationships that actually exist? The academic psychologist tends to minimize errors of incautious assertion at the expense of relatively common Type II errors. The clinician often acts on the basis of weakly supported propositions because of the dangers of ignoring potentially significant associations. But of course there may also be some risks in presuming relationships which do not have any basis in reality. This step requires that you

(x) Work out the implications in specific terms.

Therapeutic change depends, *inter alia*, upon persuasion (providing reasons why the client should change his/her attitudes and behavior); teaching (all therapies, it might be said, involve new learning); and the provision of explanations (reframing; cognitive restructuring).

Insight is not rejected as a facilitative therapeutic agent. Yelloly (1972, p. 147) states that:

> Awareness can operate in a number of ways. The sheer provision of accurate information may correct a false and erroneous belief and bring about considerable change in behavior. Prejudice for instance, may be diminished by new information which challenges the prejudiced belief. And in human beings (pre-eminently capable of rational and purposive action) comprehension of a situation, knowledge of cause and effect sequences and of one's own behavior and its consequences, may have a dramatic effect on manifest behavior. Thus to ignore the role of insight is just as mistaken as to restrict attention wholly to it.

5.02.7.2 Explaining to Parents

The attempt to "make sense" of complicated problems for (say) parents and teachers, depends upon the particular circumstances of the case, but also on the ability of the practitioners to translate technical matters into plain, unpatronizing language. Although behavior therapy is not primarily an insight-based therapy, undoubtedly the understanding of its rationale and how it applies to the individual child facilitates the process of change, as mentioned above (Herbert, 1987b).

A functional analysis can be a rich source of insights for the client. A connotation of such an analysis is that the behaviors under consideration serve a purpose, that is, are functional (dysfunctional though they may appear to the professional eye) for the individual. Clinical psychology is full of examples of this kind of functionalism; therapists commonly talk of the secondary gains arising from clinical problems. Their implications for the individual's well-being and effective functioning provide a diagnostic guideline for the therapist and an insightful view of causation for the client. The meaning of the problems for the child and indeed for his or her family—the sense made of them and the payoff they provide—constitute a vital element of the formulation conveyed to the clients.

In behavioral work, in the author's opinion, explanations in terms of a functional analysis can operate at two levels. At its simplest, behavior is a function of certain contingent stimuli, originating in the person's internal and external environment. Here, the important questions are: "what triggers (elicits) the phobia?" or "what reinforcement does the child get for behaving in this antisocial way?" At a more interpretive level, the child's behavior may have the function of solving (or attempting to solve) a developmental or life problem. To make sense of it, one might ask (*inter alia*): "what immediate "solutions" (even if self-defeating in the longer term) do the child's actions provide for himself or herself?" Also, "what purpose does the child's behavior serve in terms of his or her family life and its psychological and social dynamics?"

A clinical formulation which is being explained to parents might sound something like this:

> Andrew has not yet learned to control his temper. He "lets go" in a frightening tantrum—banging his head, kicking, screaming, and yelling—when he cannot get his own way, also when you try to insist on his doing something, refuse his commands, or attend to people other than himself at a time when he wants your undivided attention. The result (usually) is that he achieves his goal, he coerces you both into giving way—a very rewarding state of affairs seen from his point of view; a very unrewarding (and sometimes humiliating) state of affairs seen from your perspective. Occasionally you stick to your guns which means that Andrew has been getting rather inconsistent messages; the consequences of his undesirable actions are not predictable. Sometimes (but rarely) you punish his unacceptable behavior, generally when there are visitors. Sometimes you ignore it, for example, at the supermarket. Generally you "reward" it and thus make it more likely to recur, by giving in to him. Andrew has learned to make this outcome

more likely by escalating the tantrums into very violent and therefore frightening episodes. It now has to be made quite clear to him that his bad behavior will have consequences that are not only unrewarding, but also unpleasant enough to make him relinquish his tantrum. You have tried smacking which you admit makes him worse and you miserable. A method called response-cost will be used—in essence, fining his tantrums. At the same time it will be made very beneficial for him to be more obedient, to ask nicely and to control his temper. His successes will be recorded on this chart and show him how he can earn treats when he has collected a certain number of stickers.

5.02.8 THE "HOW?" QUESTION—IMPLEMENTING AN INTERVENTION

Client commitment and resistance to change are among the most critical features to assess and manage when implementing a successful intervention of whatever kind. The collaborative approach as elaborated by Webster-Stratton and Herbert (1994) is designed, by means (*inter alia*) of self-empowering strategies, the use of relationship, respectful attention to clients' feelings and ideas, and the use of metaphor and humor, to stimulate their interest and incentive to change, and to overcome resistances. Herbert and Wookey (1997) have been able to confirm the effectiveness of such process variables in a succession of parent groups.

The self-empowering strategies are designed to enhance self-esteem and perceived self-efficacy. Perceived self-efficacy is a significant item in any formulation of the likely success of such an approach (see Webster-Stratton & Herbert, 1994). Bandura (1977) is of the opinion that human behavior is subject to two major categories of influence: efficacy expectations (the conviction that one can successfully carry out the behavior required to produce a given outcome) and outcome expectations (the estimate that one's behavior will lead to certain outcomes).

These constituent parts of this crucial notion of perceived self-efficacy are distinguished because a mother or father may believe that a particular course of action (e.g., a behavioral program) will produce certain outcomes, that is, an improvement in their child's behavior. However, they may have serious misgivings as to whether they have the wherewithal (e.g., patience and consistency) to bring about such a desirable outcome. All psychological procedures designed to bring about change, whatever the type, are thought (by some psychologists) to depend on beliefs about the level of skill required to bring about an outcome and the likely end result of a course of action.

Efficacy expectations are thought to be the most important component. The main effect on outcome expectations is through the strengthening of efficacy expectations ("I *am* able to do it!"). Successful helping thus depends, in this view, on the degree to which the interventions create or strengthen the client's expectations of personal efficacy. It appears that verbal persuasion has only relatively weak and short-lived effects on such expectations. Performance accomplishments, on the other hand, have the most powerful effects, hence the concentration on "doing" (e.g., behavior rehearsal, modeling, role-play, homework tasks) in behavioral parenting training (Webster-Stratton, & Herbert, 1994).

5.02.8.1 The Collaborative Approach

Webster-Stratton and Herbert (1993) are of the opinion that the collaborative approach to clinical work by empowering clients is highly effective in producing favorable outcomes with the conduct disorders (see Herbert, 1995; Herbert & Wookey, 1997; Patterson & Forgatch, 1985; Spitzer, Webster-Stratton, & Hollinsworth, 1991). In a collaborative relationship:

> ... the therapist works with parents by actively soliciting their ideas and feelings, understanding their cultural context, and involving them in the therapeutic experience by inviting them to share their experiences, discuss their ideas, and engage in problem-solving. The therapist does not set him/herself up as the "expert" dispensing advice nor lectures to parents about how they should parent more effectively; rather, the therapist invites parents to help write the "script" for the intervention program. The therapist's role as collaborator, then, is to understand the parents' perspectives, to clarify issues, to summarize important ideas and themes raised by the parents.... (Webster-Stratton & Herbert, 1994, p. 108)

The partnership between clients and practitioner, it is suggested, has the effect of giving back dignity, respect, and self-control to parents who are often seeking help for their children's problems at a vulnerable time of low self-esteem, self-blame, guilt, and learned helplessness (Herbert & Wookey, 1997).

5.02.8.2 Rigorous Evaluation

Data collection begun in the baseline period continues throughout the intervention period. It is vital to keep a close watch on what happens in the early stages to ensure that the program is being followed correctly and any unforeseen problems that arise are dealt with quickly. This is the rigorous evaluation component of the ASPIRE process.

In the light of the data collected relating to the target behavior(s), or any other objective information, it may be necessary to reformulate one's previous conclusions and modify the intervention in some way. In the case of behavioral work the program is flexible and if the chosen target behavior is not changing after a reasonable period of time it becomes essential to review all aspects of the work.

The following questions may be useful.

(i) Are there powerful competing reinforcers or interfering factors in the client's environment operating against the program? Can these be modified?

(ii) Are the reinforcers well chosen and effective?

(iii) Is the parent working effectively and being reinforced for his or her participation?

(iv) Are the behavioral objectives realistic? Are they within the client's repertoire?

(v) Have you proceeded too quickly? Is it necessary to go back to an earlier stage in the intervention plan?

The time for the program to end depends upon the goals established at the beginning of treatment although new (or elaborated) goals may emerge during the intervention.

5.02.9 SUMMARY

This chapter begins by stating that the piecing together of a clinical formulation is central to the practitioner's craft. The choice of the word "craft" was deliberate. The craft of the potter is an apt metaphor for the many-faceted psychological skills applied to the task of analyzing and synthesizing, into a relatively brief statement—a formulation—about complex human problems. Potters are *applied scientists* when they draw upon an empirical knowledge base for the different clays and glazes they use, and the parameters for firing the products they make. But they become artists as well, when they design and decorate their creations, and when they bring to bear a delicacy, intricacy, and sureness of touch as they shape the clay.

Undoubtedly there is something called a "clinical art," especially in the ingenuity with which an assessment and intervention are put into effect. Nevertheless, in the opinion of this author, the major part of the clinical endeavor remains a scientific one. The balance of these emphases differs according to the basic assumptions of the theoretical model adopted and the clientele one works with. Certainly therapy with children demands a good deal of imagination and "artistry," especially if they are to remain well motivated.

The chapter demonstrates how difficulties and, indeed, failures in the treatment of children's behavior problems can frequently be traced back to a lack of precision during the crucial assessment phase of a clinical contact. A scientist-practitioner trying to explain a particular phenomenon will be at pains to bring that phenomenon into "sharp focus" by describing and measuring it in all its manifestations as objectively as possible. The analysis of a problematic situation and the planning of an intervention require as much knowledge and skill as any other aspect of the clinical psychologist's input, possibly more. The ASPIRE procedures outlined for conducting such an assessment follow broadly the tried and tested scientific method of problem-solving.

The scientist-practitioner's science, however, is not, and because of the exigencies of clinical work cannot be, of the kind represented by what might be called "scientism"—a pharisaical insistence on the letter rather than the spirit of scientific method. There has to be room for intuition, insight, and creativity as long as they are checked and validated whenever possible by rigorous evaluation. It has been said that what cannot be measured cannot be changed, a proposition that has much merit as long as measurement does not generate into a sterile obsession with minutiae. The case study is the bedrock of clinical work, and an invaluable scientific method of enquiry. It provides us with an exemplar of that unique blending of idiographic and nomothetic approaches that have their parallels in the artistic and scientific facets of clinical psychology.

5.03.1 INTRODUCTION

According to Orlinsky and Howard (1986, pp. 311–312) the therapy process refers to "everything that can be observed to occur between and within the patient and therapist during their work together." This is indeed a broad domain of inquiry; nevertheless, research on therapeutic transactions, patient and therapist characteristics, and change events during treatment have been relatively neglected by child therapy investigators. As Kazdin, Bass, Ayers, and Rodgers (1990) have reported, less than 3% of all child therapy studies have investigated treatment processes, and few studies have examined either child or therapist characteristics that could moderate treatment outcome. Although there is some evidence to suggest increasing attention to these aspects of child treatment since the 1980s (cf. Russell & Shirk, in press; Shirk & Russell,1996), much of the child therapy literature retains a restricted focus on comparisons of treatment packages or, to a lesser degree, on the evaluation of specific techniques.

The relative neglect of child therapy processes is puzzling for a number of reasons. First, from a clinical perspective, the primary experience of practicing therapists is the ongoing transactions that comprise therapy sessions. In essence, social and symbolic exchanges constitute the principle phenomena of child psychotherapy. Viewed from this perspective, one might expect the study of process to be at the forefront of child therapy research. In fact, Kazdin et al. (1990) found that child practitioners regard studies of process and its relation to outcome to be a top research priority. Yet the investigation of process remains in the background of child therapy research. Second, growing evidence from the adult psychotherapy literature has shown that variation in processes within sessions, as well as characteristics of therapists and patients, have an important bearing on treatment outcome (Orlinsky, Grawe, & Parks, 1994). Nevertheless, process research is "perhaps the area of work that is most discrepant between child and adult therapy" (Kazdin, 1995, p. 268).

Given the restricted focus of child therapy research, it is proposed to cast a broad net across empirical literatures that could inform understanding of child therapy processes. It has been argued elsewhere (cf. Shirk & Russell, 1996) that much of the child psychotherapy literature has evolved in isolation from basic developmental research that entails important implications for understanding therapeutic processes. Therefore, the approach to process issues in child psychotherapy is developmental in two ways. First, child therapy, regardless of treatment type, can be viewed as developmental process. Psychotherapy process is fundamentally concerned with the course of change over time. What makes this process developmental is that the aim of therapeutic change involves the progressive transformation of the child's basic capacities to interact competently in the world. Second, research on developmental processes in everyday, nontherapeutic contexts can have an important bearing on how the process of child treatment is understood (Shirk, 1988; Shirk & Russell, 1996). Consequently, the chapter is not restincted to studies of child therapy process *per se* but integrates research from the developmental literature where appropriate.

A number of models of therapeutic change have been advanced in the adult therapy literature (cf. Howard, Lueger, Mahling, & Martinovich, 1993; Prochaska, DiClemente, & Norcross, 1992). Common to these models is a sequential perspective on the course of therapy that delineates different phases of treatment with characteristic treatment processes. Such a framework has yet to be developed for child treatment. As a start, this review of child therapy process is organized around salient phases of treatment. Specifically, this chapter follows the "flow" of therapeutic interaction from referral to termination. Along the way factors that influence the referral process, readiness or preparation for treatment, social and symbolic exchanges in sessions, and the relation between process and outcomes are considered. The primary aim is to identify critical process issues that have relevance for the practice of child therapy and for the conduct of future research.

5.03.2 REFERRAL TO CHILD PSYCHOTHERAPY

Unlike adults, children rarely refer themselves for psychological treatment. In fact, it is not uncommon for others to be more distressed by the child's problems than is the child. Referral to child therapy typically involves judgments and decisions by other people, usually parents and teachers, in the child's life. Thus, from the outset, the process of child therapy is embedded in a social context that goes beyond the transactions between patient and therapist. In order to understand the referral process in child therapy, it is essential to examine the reactions of "referring" adults to various forms of child problem behaviors. To this end, investigators have begun to examine factors that influence parent and teacher decision making about referral to child treatment.

5.03.2.1 Parent and Teacher Perceptions of Problem Behaviors

One of the well-worn paths to the child psychology clinic begins with the parent–teacher conference. In this context, adult perceptions and appraisals of child behavior problems influence decisions about referral. Because teachers are a primary referral source, a number of investigators have examined their evaluations of children's problem behaviors. Walker, Bettes, and Ceci (1984) asked preschool teachers to evaluate the severity, long-term outcome, stability, and need for referral of three vignettes that depicted children at two ages (3.5 and 5.5 years) who presented with aggression, hyperactivity, or withdrawal. The gender of the child was also varied. Among the central findings of the study, preschool teachers tended to view disruptive behavior problems as more severe, more stable, and portending poorer long-term outcomes than problems of withdrawal.

Consistent with these evaluations, teachers were more likely to agree that disruptive children should be referred for professional help than children showing signs of withdrawal. A similar pattern of results was obtained by Weisz et al. (1988), who found that elementary school teachers rated undercontrolled problems, relative to overcontrolled problems, as more serious, worrisome, and less likely to improve. Examination of referral problems in US clinics has revealed higher rates of undercontrolled problems than overcontrolled problems. Although it is likely such differences reflect variations in prevalence rates for the two broad classes of disorders, it is also possible that differences in problem appraisal among referring adults contributes to this difference.

One implication of this pattern—that undercontrolled problems are viewed as more serious than overcontrolled problems—is that children with symptoms of depression and anxiety may be under-referred for treatment because of beliefs that such problems are transient and will diminish over time. Research, however, has indicated that internalizing problems may be more persistent than once believed, and that untreated internalizing problems constitute a risk factor for future psychiatric disorders (Ollendick & King, 1994).

An alternative approach to evaluating the "referability" of various types of emotional and behavioral problems has been advanced by Weisz and Weiss (1991, p. 267), who operationalized referability as "the frequency with which a child problem is reported as a presenting complaint at mental health clinics, relative to the frequency of that problem in the general population." Epidemiological data were collected in both the USA and Thailand with a broad-band measure of child behavior problems. Clinic records from multiple sites were coded for specific presenting problems in both countries. Referability indices were computed for specific behavioral problems for children between the ages of 6 and 11 years. Results from the US sample indicated that problems with serious implications for self or others, such as attacking other people or deliberately harming the self, were among the most referable problems. And like the results from the vignette studies, overcontrolled problems, such as perfectionism and self-consciousness, were among the least referable problems. This pattern of results suggests that the lower number of internalizing problems in clinics is not just a function of differences in problem prevalence but may reflect parental judgments about the prognosis for specific problems and the degree to which such problems can be remediated or tolerated in the home.

The foregoing studies suggest that problem type is an important contributor to decisions about clinic referral. Overall, undercontrolled problems appear to have the greatest capacity to elicit referral. Other factors, however, may influence parents' and teachers' referral decisions. A number of investigators have examined other child and family characteristics that could affect the referral process, including: child age, gender, and cultural background. In addition, numerous studies have suggested that parental characteristics, specifically parental psychopathology, are associated with perceptions of child behavior problems.

5.03.2.1.1 Child age and referral

Results from several studies have shown that younger children in the classroom are referred for mental health services at a higher rate than their older classmates (Drabman, Tarnowski, & Kelly, 1987; Tarnowski, Anderson, Drabman, & Kelly, 1990; Wisniewski, Andrews, & Mulick, 1995). Although one might expect these children to be less mature and possibly less advanced academically, Tarnowski et al. did not find significant differences in cognitive functioning or academic achievement between younger and other children in the same classroom. This pattern of findings was replicated and extended by Wisniewski et al., who also found a disproportionately high referral rate for younger children, and did not find group differences in indices of cognitive functioning or in levels of behavior problems. Thus, the disproportionate rate of referral did not seem to be attributable to "objective" age differences in the rate or severity of behavioral or academic problems.

The lack of a systematic relationship between referral and "objective" reasons for referral has suggested the possible contribution of teacher bias in the referral process. In their analysis of child characteristics associated with referral, Wisniewski et al. (1995) found that as children deviated upward from the mean in height and weight, they were referred at disportionately higher rates. This tendency was particularly prominent among younger children in the classroom. As Wisniewski et al. observed, children's physical characteristics appear to be influencing teachers' referral decisions. Younger children who are relatively large for their age may be referred at a higher rate because they are misperceived to be similar to older children on academic dimensions. Thus, when these less mature children function at a level that is discrepant with teacher expectations for the average child in the class, but appropriate for their age level, they are viewed as needing remedial services (Wisniewski et al., 1995). In essence, perceived discrepancies based on nonacademic factors (physical size) appear to contribute to teacher referral decisions. This interpretation is consistent with the formulation advanced by Masten and Braswell (in press), who propose that referral decisions are linked to judgments about discrepancies between age and the successful negotiation of specific developmental tasks. Teachers may have clear expectations for grade level, and expect all children at that level to complete specific tasks regardless of variation in age within the classroom.

5.03.2.1.2 Child gender and referral

Despite developmental evidence suggesting that parents monitor their daughters' behavior more closely than their sons', and tolerate less behavioral disruption from female children than males (Zahn-Waxler, 1993), boys are more often referred to clinics than girls. Several explanations can be offered for this apparent inconsistency. First, boys may simply evince higher rates of emotional and behavioral problems than girls (McDermott, 1996), consequently differences in prevalence rates may account for differences in referral rates. Second, although parents monitor their daughters' behavior more closely than their sons', differences in the types of problems expressed by males and females could affect referral. Given evidence for more disruptive behavior problems among males than females (McDermott, 1996), and evidence indicating that such problems are viewed as more serious by teachers and parents, gender differences in type of problem could account for gender differences in referral. Parents might conclude that disruptive, particularly aggressive, problems cannot be handled without professional help. On the other hand, the tendency to view internalizing problems as more transient and less severe may result in the underreferral of females who have been shown to express more internalizing problems, such as depression, particularly during adolescence (Nolen-Hoeksema, 1990).

In this context, the finding of Weisz and Weiss (1991) that problems are more referable for girls than for boys, at least in the USA, is somewhat surprising. Although gender did not affect the relative referability of specific problems for males and females, fighting, for example was highly referable for both genders; in general, problems were more referable for girls than boys. Thus, when girls show a specific problem, they are more likely to be referred than boys—although it is important to keep in mind that a number of problems characteristic of depression have low referability.

One area where this is particularly the case, are problems that load on the Sex Problems factor of the Child Behavior Checklist (Achenbach & Edelbrock, 1981). Although girls do not show an overall higher prevalence rate on these types of problems, when they do show such problems they are more likely to be referred than boys. Taken together, evidence for greater referability for females than males, but higher rates of male than female referral to clinics, suggests that higher rates of behavior problems, particularly undercontrolled problems, among young males relative to females account for their overrepresentation in clinics.

In summary, although parents and teachers do not report differences in the seriousness of problems when they evaluate males and females in vignettes (Walker et al., 1984; Weisz et al., 1988), differences in referability suggest that their actual referral decisions may be influenced by the child's gender, and possibly by different sex-typed expectations for boys and girls. The overrepresentation of males in clinics appears to follow from higher rates of undercontrolled behavior problems relative to females, and possibly to the under-referral of females with internalizing problems.

5.03.2.1.3 Referral and cultural background

A series of studies has revealed that culture plays an important role in adults' perceptions of child emotional and behavioral problems (Lambert, Weisz, & Knight, 1989; Lambert et al., 1992; Weisz et al., 1988; Weisz & Weiss, 1991). For example, in comparing the perceptions of American and Jamaican adults, Lambert et al. (1992) found that cultural background was related to evaluations of undercontrolled behaviors but not overcontrolled problems, such that Jamaicans seemed more concerned about disruptive problems than American adults. Cultural differences were also reported by Weisz et al., who found that Thai adults expressed less concern about both over- and undercontrolled behaviors than American adults. This pattern was also partially supported in the "referability" study of Weisz and Weiss. Undercontrolled problems, but not overcontrolled problems, were more referable in the USA than Thailand.

These findings suggest that culture may set a threshold for adult tolerance for distress about childhood problems, and that tolerance levels may vary by type of problem (Lambert et al., 1992). For example, Weisz and Weiss (1991) found that problems such as fighting, swearing, and threatening were more likely to prompt referral in the USA than Thailand, whereas the opposite was true for such problems as strange behavior, fears of school, and liking to be alone. Thus, one factor that may influence the degree to which problems are regarded as serious enough for referral is the cultural context in which they occur. It is likely that ethnic variation within the same society could exert a similar influence; however, such findings have yet to be reported. Clinical reports also have suggested that members of different ethnic groups vary in their interest or willingness to utilize professional services for child behavior problems (cf. Tharp 1991).

5.03.2.1.4 Referral and parental psychopathology

Parental accounts of child behavior problems are often presented with a strong affective valence. Consequently, parents, who are often entangled in their child's presenting problems, are not necessarily neutral reporters. This has raised concerns that parents' own affective states could bias their reports of child behavior problems. This clinical concern appears to be validated by a growing body of evidence that suggests that parental depression is associated with ratings of child behavior problems (cf. Schaughency & Lahey, 1985; Webster-Stratton, 1988). Specifically, the association between maternal depression and ratings of externalizing problems has been established in multiple studies, and has prompted some to conclude that "parent's depression rather than the child's behavior is a significant factor in the referral of these children for treatment" (Rickard, Forehand, Wells, Greist, & McMahon, 1981, p. 204).

From a process perspective, depression, or other forms of parental distress, may narrow the parent's tolerance for variation in child behavior such that minor behavioral deviations are misperceived as abnormal. Depressed parents, relative to their nondepressed counterparts, may become more distressed by typical child misbehavior, and amplify the severity of child problems in their behavioral reports. To the degree that referral is associated with parental judgments about the abnormality of behavior, the narrowed band of tolerance found among depressed parents would result in a lowered threshold for referral. In essence, referral is based on a distorted perception of child behavior problems.

In his review of research on the link between maternal depression and distorted perception of child behavior problems, Richters (1992) raised serious concerns about the existing evidence for this connection. Obviously, inferences about perceptual distortions do not directly follow from group differences in behavioral reports of depressed and nondepressed mothers. High rates of behavior problems could stem from problematic interactions in families with a depressed parent rather than from parental misperceptions. According to Richters, the distortion hypothesis requires (i) depression-related discrepancies with criterion ratings such that depressed mothers show less concordance with validated criterion than do nondepressed mothers, and (ii) evidence that the criterion rating is more reliable or accurate than maternal ratings, themselves. Based on a review of 17 studies that reported a depression–distortion link, Richters concluded that the vast majority fail to meet the foregoing criteria. Consequently, he concluded that "there appears to be no empirical foundation for the widespread belief that depressed mothers have distorted perceptions of their children's problems" (Richters, 1992, p. 496). However, as Richters wisely noted, the absence of evidence should not be confused with evidence for absence of distortion. Although existing research has revealed a relation between parental depression and child problem behaviors, the causal relationship and relative contribution of parental perceptions have not been clearly established.

Parents are in a unique position to evaluate the nature and severity of child problem behaviors, for example, they are aware of the child's behavior across contexts and over time; however, parents are often participants in or recipients of the child's problem behaviors. Consequently, parents' perceptions of their child's behavior could be influenced not just by their own affective state but by their role in their child's problem. Research in this area is virtually nonexistent; however, Reid, Kavanagh, and Baldwin (1987) have observed that abusive parents appear to view their children's behavior as more problematic than suggested by extensive behavioral observations. As Reid et al. have noted, the perception of child behavior as highly problematic may function to rationalize maltreatment by abusive parents. Such findings serve as a reminder that parents are participant-observers of their children's behavior, and that such a standpoint may contribute to biased perceptions or interpretations of child behavior.

5.03.2.2 Process Issues in Clinical Referral

Adult perceptions of child problems are an integral part of the clinical referral of children. Existing research has revealed that problem type, child age, gender, and cultural context are associated with adult perceptions of children's problems. Although there is evidence for a relationship between maternal depression and reports of child behavior problems, the accuracy of depressed mothers' perceptions has not been adequately addressed and awaits further investigation.

One of the major limitations of research on referral to child therapy is the absence of an explicit process model. Fragments of a model can be found across studies, but an integrated perspective on the relative contribution of specific judgments, for example, about the severity, abnormality, prognosis, and etiology of child problems, to referral decisions has not been advanced. As in all process research, the guiding question should be *how* do parents arrive at a decision to refer their children for treatment. For example, it is possible that referral involves the interplay between cognitive processes, such as judgments about abnormality (itself a function of social comparison processes), and emotional processes, such as demoralization following repeated failures at resolving the problem within the family. Future studies could manipulate these factors in case vignettes, for example, problem severity and intransigence, in order to evaluate their contribution to referral decisions. Other factors, such as the availability of services and parental perceptions of the efficacy of such services, are likely to contribute to the referral process as well.

5.03.3 READINESS AND PREPARATION FOR CHILD THERAPY

Treatments vary in the degree to which child participation is critical for successful outcome. Traditional child treatments such as psychodynamic, experiential, and play therapies, as well as cognitive and cognitive-behavioral therapies, require active child involvement in therapy. Although treatment tasks vary substantially across these therapies, they share the common assumption that children's active participation is essential for successful outcomes. In contrast, some child treatments such as parent management training require only minimal, if any, participation by the child in therapy sessions. Instead, parent collaboration with treatment is critical for altering child behavior (Patterson & Chamberlain, 1994). It should be noted, however, that many child behavioral treatments, such as desensitization and social skills training, require high levels of child participation in sessions.

Research on adult psychotherapy has indicated that active participation in treatment is one of the best process predictors of treatment outcome (Frieswyk et al., 1986; Gomes-Schwartz, 1978). In this context it is interesting to note that research has indicated that nearly two-thirds of all children aged between 7 and 15 years would feel negatively if they were referred to see a psychologist (Sigelman & Mansfield, 1992). Given that children appear to be "reluctant consumers" of mental health services, it is surprising that few studies have addressed children's participation in treatment and its relation to outcome.

One of the few studies to address this issue, conducted by Braswell, Kendall, Braith, Carey, and Vye (1985), examined children's level of involvement in cognitive–behavioral therapy and found that a number of verbal indicators of active participation predicted therapeutic gains. Specifically, children's tendency to make spontaneous verbal elaborations about treatment tasks and therapists" encouragement and corrective feedback appeared to be among the best predictors of change in teacher ratings of self-control. Similarly, Colson et al. (1991) found that ratings of treatment difficulty, that is, the degree to which patients' were viewed as defiant and uncooperative in treatment, were negatively associated with ratings of patient progress in a sample of hospitalized adolescents. The findings of this study, although suggestive of a link between quality of participation and treatment outcome, are compromised by the absence of independent process and outcome ratings. Despite limited empirical findings on the relation between in-session participation and treatment outcome in the child literature, clinical theory and evidence from the adult therapy literature indicate that the study of treatment participation and the factors that promote or obstruct it represent a critical area for child psychotherapy process research.

5.03.3.1 Readiness for Therapy

Some years ago, Anna Freud (1965) recognized that a number of developmental factors could interfere with children's willingness to participate in therapy. A major obstacle, according to Freud, is the child's lack of awareness or acknowledgment of his or her own emotional or behavioral problems. As she noted, due to their immaturity, children often have "no insight into their abnormalities" and that, accordingly, "they do not develop the same wish to get well and the same type of treatment alliance" as adults (Freud, 1965, p. 28). In the absence of self-acknowledged emotional or behavioral problems, children do not experience a need for change, and, consequently, a need for treatment. Moreover, when problems are acknowledged, Freud observed that children typically locate the source of the problem in the external world and prefer environmental or situational solutions to their problems. This type of problem construal is incongruent with forms of therapy that focus on child-centered treatment processes such as altering affect regulation strategies, modifying cognitive patterns, or developing specific social skills. Furthermore, even when children recognize emotional or behavioral problems, and acknowledge a role in them, they do not necessarily view others as useful agents of change. Consequently, the degree to which children view interpersonal coping strategies as useful or effective could influence their willingness to utilize psychotherapy to deal with their difficulties. Given these potential obstacles, treatment engagement represents one of the major challenges of child therapy.

In an effort to integrate multiple processes that could influence children's willingness to participate in therapy, Shirk (Shirk, 1990; Shirk & Saiz, 1992) presented a developmental social–cognitive model of alliance formation. Elaborating on Anna Freud's clinical insights (Freud, 1965), Shirk hypothesized that developmental variations in children's cognitions about their own emotions and behaviors could contribute to their willingness to engage in the process of therapy.

5.03.3.1.1 Problem acknowledgment

The first source of social cognitive influence is hypothesized to be children's recognition and acknowledgment of emotional or behavioral problems. Children who do not acknowledge problems are expected to be more difficult to engage in a process that involves problem remediation. Moreover, from a developmental perspective, the ability to recognize one's emotional and behavioral difficulties should be related to the development of self-evaluative, especially social comparative, processes. Younger children, lacking in perspective-taking ability, find it difficult to distinguish between wishful images of self and actual characteristics (Leahy & Huard, 1976). In fact, research by Harter (1988) has indicated that younger children, especially those of preschool age, overrate competencies and minimize difficulties. Furthermore, there is some evidence to suggest that this tendency is amplified in clinic populations (Vondra, Barnett, & Cicchetti, 1989; Zimet & Farley, 1986). In fact, it is not uncommon to find significant discrepancies between parent and child evaluations of problem behaviors and emotions (Achenbach, McConaughy, & Howell, 1987; Kazdin, French, & Unis, 1983).

In a study with a heterogeneous sample of psychiatrically hospitalized children, Shirk, Saiz, and Sarlin (1993) found that children's level of problem acknowledgment at admission was predictive of therapists" ratings of the treatment alliance 3 weeks later. This finding is consistent with earlier research indicating that children's reluctance to participate in therapy is linked to problem denial (Taylor, Adelman, & Kaser-Boyd, 1985). Closer analysis of the alliance data indicated that problem acknowledgment predicted the affective quality of the therapeutic relationship but not children's level of collaboration with therapeutic tasks. The failure to find a relationship with task collaboration could be due to methodological limitations. First, task collaboration was narrowly defined as verbalization about problems and feelings; and, second, verbalization was assessed through global ratings by therapists. It is possible that specific coding of verbal interactions by observers would have yielded different results. In fact, research by Russell, Bryant, and Estrada (1996) has shown that child therapy sessions in which there is a positive therapeutic relationship are characterized by distinctive patterns of child–therapist discourse. However, the link between child problem acknowledgment and involvement in treatment processes, including verbal interaction, awaits further investigation.

5.03.3.1.2 Problem attributions

The second postulated source of social-cognitive influence involves children's attributions for their presenting problems. Research on adult psychotherapy has indicated that patients who view their problems as externally imposed are not likely to benefit from treatment (Kirtner & Cartwright, 1958; Salzman, Luetgert, Roth, Creasant, & Howard, 1976). Similarly, children may acknowledge the existence of problems but locate the source of their problems in the external environment. Although the child's attributions may be accurate in some cases, and consistent with certain forms of therapy, for example, family therapy, for child-centered treatments such an attributional pattern could undermine willingness to participate in child-focused interventions.

Developmental research indicates that children's understanding of the causes of behavior shows a general trend from external to internal attributions with increasing age (Shirk, 1988). As children acquire complex concepts of internal, psychological functioning, and develop the capacity to reflect on such processes, these concepts can be applied to observed behavior, including their own problematic behavior. As a result, internal attributions for behavior problems should increase with age during middle childhood. In fact, research on children's understanding of deviant behavior has revealed that children increasingly attribute such behavior to internal, psychological processes with increasing age (Coie & Pennington, 1976).

Two treatment outcome studies point to the potential relevance of children's attributions for treatment process. In the first, Bugental, Whalen, and Henker (1977) predicted that children's causal attributions for academic outcomes would moderate the effect of two types of treatment, a 6 week self-instructional training program (internal locus) or a 6 week social reinforcement program (external locus) for hyperactive boys. It was predicted that outcomes would be more positive for subjects with attribution-congruent treatments, for example, social contingency treatment for children with external attributions, than for those with incongruent treatments. Although the treatments did not produce changes in teacher ratings of disruptive behavior, subjects in the attribution-congruent treatments showed greater improvement on a measure of cognitive functioning. Thus, it appeared that treatment outcome was, in part, a function of the match between child attributional pattern and locus of treatment. It is possible that children in attribution-incongruent treatments were less engaged, or viewed the treatments as less acceptable, and therefore benefited less than children in congruent treatments; however, this process hypothesis was not evaluated.

Research by Weisz (1986) on the relationship between control-related beliefs and treatment outcome in child therapy carries implications for the link between problem attribution and treatment involvement. According to Weisz, children vary in the degree to which they view outcomes as contingent on their own behavior or efforts. In a therapeutic context, children who believe that problem resolution is contingent on altering their own behavior should be more willing to engage in therapeutic problem solving than children who view problem solutions as independent of their efforts. As Weisz noted, individual differences in contingency beliefs could lead to corresponding differences in therapeutic involvement, thereby resulting in differential rates of change during treatment. In a study with 8–17 year olds referred for outpatient therapy, Weisz found a significant relationship between contingency beliefs, measured prior to treatment, and total problem reduction. Although these results are consistent with the view that attributions for problems promote or obstruct therapeutic engagement, the level of treatment involvement was not directly assessed in this study. Consequently, the link between pretreatment attributional patterns and therapy process has yet to be investigated.

5.03.3.1.3 Help-seeking expectations

A third source of social cognitive influence involves children's beliefs about the usefulness of other persons in resolving emotional or behavioral difficulties. From a developmental perspective, beliefs about the responsiveness and effectiveness of potential caregivers, including therapists, is likely to be rooted in early experiences of care (Shirk & Saiz, 1992). One of the basic tenets of attachment theory is that individuals develop internal working models of the self in relation to attachment figures that reflect the history of caregivers' reactions to the child's emotional needs and distress (Bowlby, 1988; Main, Kaplan, & Cassidy, 1985). Repetitions of infant–caregiver interactions are presumed to establish core beliefs about the availability and responsiveness of others.

Approach or avoidance patterns in times of distress are hypothesized to be linked to these core beliefs (Kobak & Sceery, 1988). Research on children's coping strategies has revealed significant individual differences in the degree to which children utilize others when confronted with psychological stressors (Garber, Braafladt, & Zeman, 1991). Among some groups of troubled children, for example, children displaying symptoms of depression, the use of others for coping with distress appears to be relatively limited (Garber et al., 1991). In fact, Garber, Braafladt, and Weiss (1995) have found that depressed girls rated mother-initiated affect regulation strategies as less effective than did nondepressed girls. Van Horn (1996) found that beliefs about the effectiveness of interpersonal coping strategies was associated with preadolescents perceptions of prior maternal care. Taken together, these results suggest that early experiences of care could shape children's expectations about the usefulness of other persons, including therapists, in helping them deal with emotional or behavioral difficulties.

Although there is growing interest in the relationship between attachment related beliefs and psychotherapy process and outcome among adults (cf. Dozier, Cue, & Barnett, 1994; Fonagy et al., 1996), this potentially fruitful area remains unexplored with children in treatment.

In addition to pretreatment social cognitions, other child characteristics could influence children's willingness to engage in therapy. For example, patterns of interpersonal problems, such as those that characterize oppositional–defiant disorder, are likely to carry over into therapeutic interactions and obstruct treatment participation. In this connection, Eltz, Shirk, and Sarlin (1995) found that the number of interpersonal problems reported prior to treatment was negatively related to the development of a working alliance among adolescent inpatients. In addition, characteristics associated with specific disorders could constitute impediments to treatment. For example, the relatively low levels of social competence and reflectiveness found among children with externalizing problems could interfere with their involvement in therapy. Surprisingly, children with externalizing symptoms do not show poorer outcomes than children with internalizing symptoms (Weisz, Weiss, Han, Granger, & Morton, 1995); however, this result could reflect the use of parent-centered interventions, for example, parent management training, rather than child-centered interventions with externalizing disorders. Among the internalizing disorders, symptoms of depression such as hopelessness, lack of energy, or social withdrawal could undermine participation in treatment (Stark et al., 1991).

In summary, studies of differential treatment responsiveness are beginning to consider pretreatment child characteristics (cf. Kazdin, 1995); however, few studies have examined these characteristics in relation to treatment process. What is needed are studies that examine relations among child characteristics that are hypothesized to promote or obstruct children's willingness to participate in treatment, specific dimensions of treatment process such as participation in treatment tasks, and variations in treatment outcome. Unlike comparisons of treatment packages, where individual patterns are typically ignored, such studies could potentially reveal patterns of "fit" between child characteristics and treatment processes that are associated with improved outcomes.

5.03.3.2 Preparation for Child Therapy

Evidence from both the adult and child psychotherapy literatures has indicated that discrepancies between client's expectations about the roles and processes of therapy and the reality they encounter in treatment can have a variety of negative effects, including willingness to sustain participation in treatment (Coleman & Kaplan, 1990; Day & Reznikoff, 1980; Frank, 1974; Strupp & Hadley, 1977). Studies with normative samples of children have shown that young children often have limited knowledge about psychologists' roles, practices, and the process of psychotherapy, but that knowledge and expectations become increasingly accurate with age (Bonner & Everett, 1982; Sigelman & Mansfield, 1992). Interestingly, there is some evidence to suggest that children's perceptions of psychologists' traits, such as smart or perceptive, become less positive with age (Sigelman & Mansfield, 1992), though overall attractiveness of a depicted therapist remains high among normative samples (Bonner & Everett, 1980). Furthermore, it has been shown that appropriateness of children's expectations are associated with accuracy of parental expectations (Day & Reznikoff, 1980). Of central importance, however, is a finding indicating that inappropriate expectations about therapy are related to premature termination from child treatment (Day & Reznikoff, 1980). This pattern of findings has prompted investigators to design preparation techniques that could counter inappropriate expectations and sustain or enhance children's participation in treatment.

A number of preparation techniques have been devised, including pretherapy preparation interviews during which the purpose, process, and roles of therapy are explained (Holmes & Urie, 1975), audiotape presentations in which a "radio announcer" and child interview a therapist about the structure, roles, and processes of therapy (Bonner & Everett, 1986), and videotape presentations in which child participants are interviewed about their experiences and/or simulated therapy process is modeled (Coleman & Kaplan, 1990; Weinstein, 1988).

One of the most consistent findings to emerge from studies of therapy preparation has been that prepared children and parents evince greater knowledge and understanding about the structure and process of therapy than their nonprepared counterparts (Bonner & Everett, 1986; Coleman & Kaplan, 1990; Day & Reznikoff, 1980; Weinstein, 1988). However, the impact of this increased knowledge and understanding on therapy process and outcome is less clear. Results are mixed with regard to preventing premature drop-out from therapy. For example, Holmes and Urie (1975) found that prepared clients were less likely to terminate therapy prematurely than nonprepared clients, whereas two other studies failed to demonstrate this effect (Day & Reznikoff, 1980; Weinstein, 1988). Day and Reznikoff did find that prepared families had fewer failed or cancelled appointments than nonprepared families. Thus, the impact of these preparatory interventions on maintaining participation in treatment has yet to be clearly established. In fairness, research in this area has been hampered by small, heterogeneous samples that may obscure preparatory effects. However, as Weinstein has noted, the modest impact of preparatory interventions may reflect the fact that most interventions have not been guided by conceptual models of treatment engagement.

Another aim of preparatory interventions has been to enhance children's active participation in therapy. Several studies have examined relations between therapy preparation and indices of treatment process. Unfortunately, the results have been disappointing. For example, Day and Reznikoff (1980) examined the relationship between preparation and child verbalization in therapy. Preparation consisted of videotaped modeling of children talking in therapy. Despite the close relation between the preparation technique and the measure of process, comparisons of verbal samples from three sessions failed to show an effect for preparation. In a related study, Weinstein (1988) examined the relation between preparation and children's ability to adapt to the client role. Adaptation to role was assessed by child and therapist questionnaires that tapped children's comfort with therapy and their communication with the therapist. Again the preparatory intervention involved children modeling active participation in treatment. There was also no effect for preparation on either the quality of the therapeutic relationship or the character of communication. In one of the only studies to examine preparation in relation to outcome, Coleman and Kaplan (1990) found that mothers in the prepared group reported a significantly greater decrease in problem behaviors by the fourth session than did nonprepared mothers. Unfortunately, no results were reported for post-treatment outcomes; consequently, it is not clear whether these short-term effects reflected transitory changes in perceptions or enduring, enhanced outcomes. Consistent with these findings, Bonner and Everett (1986) found that preparation increased parents' and children's expectations for positive treatment outcomes. Thus, it is possible that preparation influences parents' prognostic expectations which are reflected in more positive perceptions of their children's problems relative to pretreatment. Alternatively, changes in child and parent outcome expectations could have an immediate impact on child behavior problems that may or may not endure over the course of treatment. The fact that prepared children did not report greater behavioral improvement than nonprepared children favors the interpretation that preparation may influence maternal perceptions of child problems. Research in this area would be advanced by evaluating the durability of these effects, and by the assessment of change by sources who are blind to preparation condition.

In summary, despite consistent evidence showing that treatment preparation enhances parents' and children's understanding of therapy, evidence for the impact of improved understanding on therapy process is quite limited. It is possible that other therapist, child, and family characteristics exert a greater influence on treatment participation than general knowledge of and expectations for therapy. The goodness of fit between child and therapist or parent and therapist is likely to be a powerful determinant of treatment involvement and continuation; however, research on therapist–client matching in child treatment lags far behind the adult literature (cf. Beutler, 1991). In fairness, few studies have examined the relation between preparation and treatment process; consequently, it is probably premature to dismiss such interventions as ineffective. However, research on treatment preparation could be improved by a closer analysis of child and parent cognitions that interfere with treatment participation. Targeting specific "interfering" cognitions could prove to be more effective than interventions aimed at increasing general knowledge about the structure and process of therapy.

5.03.3.3 Process Issues in Readiness and Preparation for Therapy

Initiation of child therapy is complicated by the fact that children rarely seek psychological services on their own. Youngsters often enter therapy with considerable reluctance that is frequently associated with (i) negative perceptions of therapy, (ii) lack of problem acknowledgment, and (iii) lack of choice in the decision to seek help (Taylor et al., 1985). These findings suggest that children's cognitions about therapy and their own difficulties, as well as their control-related beliefs and help-seeking expectations, may impact their willingness to engage in treatment. Unfortunately, research on readiness and preparation for child therapy is marked by a number of major limitations.

First, and perhaps most striking, is the dearth of validated measures of child treatment participation. Before investigators can identify predictors of treatment involvement, conceptual and operational definitions of positive participation must be advanced and assessed. It should be noted that a few studies have produced promising leads. For example, research by Braswell et al. (1985) suggests that children's verbalizations in sessions can be used as markers of active involvement. Of course, given the fact that verbal activity in therapy varies with age (Lebo & Lebo, 1957), and that different forms of therapy rely on verbal interaction to varying degrees (Russell, Greenwald, & Shirk, 1991), a single index of verbal participation is not likely to be an adequate measure of involvement for different forms of treatment and for children at different developmental levels. In related research, Estrada, Russell, McGlinchey, and Hoffman (1994) developed an observational rating scale for identifying dimensions of participation in child therapy sessions. Factor analysis of ratings of child behavior produced three factors that the authors labeled therapeutic relationship, therapeutic work, and readiness. The therapeutic work factor was defined by high loadings on items assessing productivity, understanding, exploration of feelings, and engagement. Given that the work factor was derived from observations of psychodynamic therapy, it is not clear whether similar factors would emerge from ratings of other types of treatments, or if other indicators of active participation would be more relevant in other forms of child therapy.

Although these initial attempts to operationalize therapeutic participation appear promising, they raise two critical issues. The first is that the character of treatment participation is likely to vary across types of child therapies. Consequently, research in this area will benefit from decomposition of the stream of therapy process into specifiable tasks (Greenberg & Newman, 1996). Identification of therapy tasks and their component features will provide an anchor for operational definitions of active participation or therapeutic collaboration.

Second, treatment tasks are likely to vary according to children's developmental level (if therapists are gearing their interventions to children's capacities). Thus, a brand-name treatment, such as cognitive-behavioral therapy, may involve different tasks for children at different ages, or if it is developmentally sensitive the components of specific treatment tasks could vary developmentally, for example, tasks such as self-instructional training might be simplified for younger children.

A second major limitation to research on readiness for therapy is that the conceptual and empirical focus has been restricted to the individual child. One of the distinctive features of child therapy is that it occurs in the context of ongoing relationships with other care-givers, typically parents. Research on parent management training, in which parents are the primary participants, has indicated that maternal depression and antisocial behavior predict initial resistance in therapy (Patterson & Chamberlain, 1994). Yet the contribution of parent or family factors to child treatment participation has been largely unexamined. In an exploratory study, Raney, Shirk, Sarlin, Kaplan, and During (1991) found that adolescent inpatients' perceptions of their parents' collaboration with the treatment team was associated with therapists' ratings of the individual treatment alliance later in treatment. Although preliminary, these results suggest that alliance formation in individual treatment may be influenced by the parents' relationship with the therapist, or at least by the child's or adolescent's perception of that relationship. Such potential effects are worth investigating, as they redirect attention to the broader social context of children's participation in treatment.

A final limitation is the virtual absence of studies of in-session transactions that could account for variation in child participation. Again, research on parent management training has revealed that pretreatment characteristics of parents account for initial levels of resistance, but that the nature of the transactions between parent and therapist predict changes in resistance (negative participation) over the course of treatment (Patterson & Chamberlain, 1994). Early 1970s child therapy research has shown that variation in therapist-offered levels of empathy, regard, and genuineness are associated with child verbal behavior in sessions (Siegel, 1972).

However, this type of research, linking therapist behavior with child involvement, has not developed up to 1997. Similarly, despite interest in child characteristics that predict participation in therapy, studies of therapist characteristics and their impact on child treatment participation are lacking. In the 1970s, Ricks (1974) demonstrated that child therapists trained in the same treatment orientation vary substantially in the way they relate to child patients, and that these differences are associated with differential treatment outcomes. Similarly, Alexander, Barton, Schiavo, and Parsons (1976) found that therapist relationship characteristics, such as warmth and humor, accounted for substantial variance (45%) in treatment outcome in functional family therapy. Despite these promising leads, research has remained focused on the evaluation of treatment packages while neglecting the therapist who delivers the treatments. Overall, then, research in this area should shift its focus from the individual child to encompass both child and therapist, and to the characteristics that define productive and unproductive therapeutic dyads.

5.03.4 IN-SESSION TRANSACTIONS IN CHILD THERAPY

A major focus of psychotherapy process research is on transactions that occur during face-to-face meetings between patient and therapist. Often these transactions are studied in their own right with the aim of discovering what actually comprises "therapy" of one type or another. Less frequently, aspects of transactions are measured and related to outcomes at the session or treatment level. Among the most salient aspects of child therapy transactions are interpersonal and symbolic exchanges between child and therapist. Both have been posited to contribute to variation in treatment outcome (cf. Shirk & Russell, 1996), and both have received some attention from child therapy investigators.

5.03.4.1 Interpersonal Transactions in Child Therapy

Child psychotherapy, regardless of treatment type, occurs in an interpersonal context. For some time, interpersonal processes have figured prominently in the adult psychotherapy literature, and reviews have indicated that characteristics of the relationship between patient and therapist are among the best process predictors of treatment outcome (Horvath & Luborsky, 1993). Although research on interpersonal processes in child psychotherapy is relatively limited, a review of child process reveals an enduring, but thin, line of inquiry on interpersonal processes in child treatment (cf. Russell & Shirk, in press). A review of this literature also indicates that interpersonal and relationship processes have been conceptualized in a number of ways.

Two basic models of the interpersonal processes in child treatment are prominent. The first conceptualizes relationship processes as a means to an end. The quality of the therapeutic relationship, and the transactions that contribute to relationship quality, are viewed as the foundation for the implementation of other (active) technical interventions. In essence, the relationship functions to promote or obstruct collaboration with treatment tasks that are posited as active change mechanisms. Interpersonal transactions that contribute to a positive relationship between child and therapist enable the child to work purposefully on resolving problems. This conceptualization is found in most models of the therapeutic alliance where a distinction is often made between the affective quality of the relationship and the quality of treatment collaboration (cf. Bordin, 1979; Horvath & Luborsky, 1993; Shirk & Saiz, 1992). Thus, despite substantial differences in the nature of treatment tasks, psychodynamic and cognitive-behavioral approaches appear to share this basic conceptualization of the therapeutic relationship. This conceptualization might be termed the indirect model of interpersonal process in child treatment. Although relationship processes are necessary for successful outcome, their influence on outcome is mediated through the child's active participation in treatment tasks. Relationship processes facilitate the operation of technical interventions, ranging from interpretation to practicing consequential thinking.

An alternative conceptualization views relationship processes as active change mechanisms. Thus, rather than positing an indirect relation between interpersonal processes and treatment effects, this perspective holds that interpersonal transactions have an unmediated impact on treatment outcome. This view might be termed the direct model of interpersonal process in child therapy, and takes its clearest form in treatments that emphasize "corrective relationship experiences."

Two child treatment approaches have emphasized the "corrective" nature of therapeutic transactions, but with somewhat different interpretations of the corrective process. The first can be found in client-centered models of child therapy. Here, the provision of a warm, accepting, and nonjudgmental relationship is viewed as a catalyst for self-propelled development (Axline, 1947). The second is found in psychodynamic, especially analytic, models that emphasize the role of transference in treatment process. A version of this perspective holds that children enter therapy with pathogenic beliefs that are "tested" in relation to the therapist (Gibbons & Foreman, 1990). Therapist actions in response to these interpersonal tests can either confirm or disconfirm the underlying pathogenic beliefs that prompt the behavior. The relationship serves a corrective function insofar as therapeutic transactions disconfirm pathogenic expectations. Although corrective processes are conceptualized differently in these two approaches, both assume that interpersonal processes are directly responsible for therapeutic change. It is interesting to note that in the adult literature, relationship processes have been shown to have a direct effect on treatment outcome even among treatments that emphasize technical operations, such as cognitive therapy (Burns & Nolen-Hoeksema, 1992). Thus, relationship processes might exert both direct and indirect effects on child outcomes, even among treatments that focus on collaboration with specific therapeutic tasks.

5.03.4.1.1 Research on interpersonal processes in child therapy

Although research on relationship processes is relatively limited, studies based, often implicitly, on either the direct or indirect model of interpersonal process can be found. One of the clearest examples of research based on the direct model comes from studies on the impact of variations in therapist-offered conditions of warmth, genuineness, and accurate empathy on treatment outcome. For example, Truax, Altman, Wright, and Mitchell (1973) compared the outcomes of a small sample of children described as mildly disturbed who received either relatively high or low levels of therapist-offered relationship conditions during treatment. Levels of therapist warmth, genuineness, and empathy were assessed during two sessions, and conditions were categorized by a median split. Outcomes, largely measures of adjustment, were assessed from multiple perspectives, including parent, therapist, and independent psychometrician. Regarding the impact of high or low levels of therapist conditions, the results were mixed. No group differences were found for psychometrist ratings; however, both therapist and parent ratings of overall change in adjustment showed significant effects for condition. Consistent with expectations, children who received high levels of therapist-offered conditions showed significantly greater benefits than their low-condition counterparts; in fact, children who received low levels of therapist-offered conditions showed deterioration on five times as many measures of specific outcomes as children receiving high levels. The authors interpreted these findings in a manner consistent with the direct model of interpersonal process, namely that relationship quality, or at least the type of relational response offered by the therapist, exerts a significant impact on treatment outcome. The study, however, was compromised in a number of ways. Children were not randomly assigned to therapists who were identified as high or low on the provision of warmth, genuineness, and regard prior to treatment. Consequently, differences in outcome might reflect unequal distributions of recalcitrant children across conditions. Furthermore, given that therapists were classified on the basis of their responses to treated children, difficult children might not have elicited high levels of therapist-offered warmth, genuineness, and empathy. Therapist-offered conditions, then, might be related to outcome, not because of children's differential responsiveness to variation in therapist-offered conditions but because children who are more or less difficult to change differentially elicit these conditions from therapists. Finally, it is important to note that interpersonal process is defined in terms of the behavior of only one of the interactants, that is, in terms of the type of therapist-offered relationship. The quality of the dyadic relationship as it develops between therapist and child, or even as it is experienced by the child, is not considered.

Many of these serious limitations are overcome in Kendall's (1994) randomized clinical trial for the treatment of anxiety disorders in children. As part of this manualized, cognitive-behavioral intervention, children's perceptions of the therapeutic relationship were assessed in order to examine possible relations with outcome. Items on the scale referred to children's feelings for the therapist and perceptions of the quality of their relationship with the therapist. In this controlled outcome study there was some, albeit limited, evidence for associations between perceived relationship quality and indices of treatment outcome. Approximately 30% of correlations between relationship quality and outcome were significant in the predicted direction; however, the majority of these involved shared source variance (child self-reports). The strongest pattern of results was between perceived relationship quality and child reports of changes in symptoms of anxiety and depression, with significant less improvement for those cases reporting poorer relationships than those reporting more positive relationships. Although the study did not provide strong evidence for the role of relationship factors, the tendency for most children to report positive relationships with their therapists may have limited variability and attenuated relationships with outcome.

Clearly, the study represents a significant advance over earlier work on relations between interpersonal process and outcome. Technical aspects of the treatment were controlled, children were randomly assigned to therapists who delivered the "same" treatment, and the quality of the relationship, rather than behaviors of one participant were assessed. With respect to interpersonal processes, however, the study is limited in several ways. The quality of the relationship was assessed from only one perspective which yielded limited variability, and relationship quality was assessed at only one point in time, at the end of treatment. Thus, it is possible that children's experience of symptom reduction could have contributed to their evaluation of the therapeutic relationship.

A study by Eltz et al. (1995) examined relationships among maltreatment experience, therapeutic relationship formation, and treatment outcome in a heterogeneous sample of psychiatrically hospitalized adolescents. Like the previous studies, this investigation is consistent with the direct model of interpersonal process; however, two advances are noteworthy. First, the quality of the therapeutic relationship was assessed from both therapists' and adolescents' perspectives; and, second, the relationship was measured at two points in time during the course of treatment. The latter enabled the investigators to examine patterns of relationship formation in a rudimentary manner. The study revealed that adolescents who showed more positive change in relationship quality, regardless of maltreatment status, evinced greater treatment gains across sources of outcome ratings relative to those showing less positive patterns of relationship development. These results suggest that changes in the pattern of relationship quality may be a better predictor of outcome than "one-shot" assessments. The more consistent pattern of associations between relationship quality and outcome in this study compared to Kendall's (1994) trial might reflect important differences in the types of children treated or in types of treatments delivered. In the latter study, patients were seriously disordered and showed marked variability in their capacity to form a therapeutic relationship. Furthermore, inpatient psychotherapy was not manualized, but instead focused on processing relationship issues. In this context, relationship quality may be the primary active ingredient of therapy, in contrast to treatments that rely on compliance with specific therapeutic tasks. Of course, the lack of control over the delivery of therapy raises the possibility that the association between relationship quality and outcome are confounded with unexamined technical differences across treatments.

In summary, these three studies provide relatively clear examples of existing research on interpersonal processes in child therapy based on the direct model. According to this perspective, the quality of the therapeutic relationship is assumed to have a direct bearing on variations in treatment outcome. Although progress can be detected across these studies, evidence for a direct relation between relationship quality and outcome in child treatment is rather limited.

Research on the indirect model of interpersonal process in child therapy is sparse. According to this perspective, relationship quality impacts outcome by promoting or obstructing treatment collaboration. Drawing on the work of Bordin (1979) and Luborsky (1976), Shirk and Saiz (1992) developed a measure of the therapeutic alliance for child therapy that distinguished between the affective quality of the relationship and collaboration with treatment tasks. Consistent with the indirect model, Shirk and Saiz hypothesized that a positive relationship between child and therapist would promote collaboration with therapy tasks. In a study with a diagnostically heterogeneous, hospitalized sample of 7–12 year old children who were seen in short-term dynamically oriented therapy, children and their therapists rated both dimensions of the working alliance. Reliabilities for both therapist and child ratings ranged from acceptable to excellent. Moreover, child and therapist perspectives on the affective quality of the relationship were moderately correlated. For both therapist and child reports, the affective quality of the relationship was positively associated with task collaboration, in this case, verbalization of feelings and problems. The results were consistent with the prediction that the affective quality of the relationship potentiates task collaboration. However, inferences of directionality are limited by the fact that the alliance was assessed at only one point in time; thus it is possible that children who establish a collaborative relationship feel positively about their relationship with their therapist, and are viewed by their therapist in a positive light. Confidence in the hypothesized relation between affective quality and task collaboration would be increased through the assessment of the alliance at multiple points in time, and by supplementing participant reports of task collaboration with independent observational ratings of involvement in specific therapeutic tasks. The major limitation of this study, however, was the absence of data on the relation between alliance and outcome; consequently, neither direct nor indirect effects could be assessed.

Along similar lines, Estrada et al. (1994) developed observational scales to assess dimensions of participation in child therapy. Factor analyses of 117 session segments revealed 3 therapist and 3 child factors. One of the child factors and one of the therapist factors concerned the quality of the therapeutic relationship. Items such as empathy, warmth, and positive relationship loaded on the therapist factor; and in a complementary manner items such as trust and openness loaded highly on the child relationship factor. There was significant covariation between independent ratings of child and therapist relationship quality. In addition, factors emerged for both child and therapist ratings that referred to involvement in the tasks of therapy, what Estrada et al. labeled therapeutic work. Again, child and therapist ratings were significantly correlated. Furthermore, in keeping with the indirect model, there was evidence to suggest that the quality of the relationship is associated with involvement in therapeutic work. Children with more positive relationships evinced higher levels of work than children who were rated as having less positive relationships. Moreover, ratings of technical lapses by the therapist, such as low responsiveness or inattentiveness, were negatively associated with the quality of the child's relationship with the therapist. These results suggest that relationship quality and task collaboration represent distinguishable aspects of the working alliance with children, and that they are associated in predictable ways. However, the directionality of this association remains ambiguous because process factors were assessed at the same point in time. In fact, the finding that therapist technical lapses are associated with the child's relationship factor is suggestive of an alternative account, namely that relationship quality is a function of the therapist's technical skill. For example, therapists who are adept at introducing treatment tasks and stimulating participation may be viewed quite positively by their child patients. Finally, like the Shirk and Saiz (1992) study, this investigation was aimed at scale development and not at evaluating process–outcome relations. As a result, the indirect model of interpersonal process has yet to be tested.

Other investigators have assessed aspects of the therapeutic relationship and/or involvement in treatment tasks. As mentioned, Braswell et al. (1985) have operationalized involvement in terms of child and therapist verbal behavior, but they did not examine this characteristic in connection with relationship quality. Smith-Acuna, Durlak, and Kaspar (1991) assessed both child and therapist experiences of therapy and found reliable dimensions corresponding to affective quality and interactive behavior; however, it was not clear that the latter dimension reflected therapeutic work. Moreover, no significant relations were found between therapist and child ratings of either dimension; however, associations within perspective were not reported. Finally, Patterson and his colleagues (Chamberlain, Patterson, Reid, Kavanagh, & Forgatch, 1984; Patterson & Chamberlain, 1994) have developed a microanalytic coding system to assess cooperative or resistant behavior by parents in parent management training. Although this line of research has yielded important findings on factors that influence resistance, and on the relation between resistance and outcome, as is discussed later in this chapter, quality of relationship is subsumed under resistant or cooperative behavior. As such, the parents' feelings about the therapist are not viewed as a separate component of the treatment relationship, although therapist behaviors that are often viewed as facilitators of relationship quality are examined separately.

In summary, research examining either the direct or indirect models of interpersonal process in child treatment is relatively sparse. One of the most glaring limitations in this area of investigation is the virtual absence of studies that have adequately assessed both process and outcome. Given the clinical emphasis on the importance of the therapeutic relationship for successful outcome across multiple types of treatments, research that addresses multiple dimensions of the relationship at multiple points in treatment, and relates these dimensions, not just with each other but with treatment outcome, is desperately needed.

5.03.4.2 Process Issues in Interpersonal Transactions

In addition to the virtual absence of research linking interpersonal processes with treatment outcome, a number of other limitations characterize this line of investigation. First, there has been a tendency to treat the therapeutic relationship as a static entity. Most studies evaluate the relationship at one point in time and fail to assess variations in relationship patterns over the course of treatment. There have been some noteworthy exceptions. For example, Siegel (1972) examined changes in child verbalizations as a function of high and low levels of therapist-offered conditions across multiple sessions of dynamically oriented therapy. But, like most studies in this area, relations with outcome were untested.

Second, almost no studies have conceptualized or assessed interpersonal processes as transactions consisting of linked sequences of exchanges between child and therapist. Instead, the focus has been on child or therapist experience of the relationship, an important aspect of interpersonal process, or on ratings of individual behavior. Interestingly, one of the earliest studies of child therapy process, conducted by Moustakas and Schalock (1955), examined contingencies, albeit in rudimentary way, between child and therapist behaviors. This approach to interpersonal process in child treatment remains underdeveloped.

Finally, child process investigators have largely failed to identify critical interpersonal change events or sequences that could be predictive of outcome. For example, sequences such as the "rupture and repair" of the therapeutic alliance (Safran & Muran, 1996, p. 447) or the resolution of therapeutic impasses (Diamond & Liddle, 1996) have been postulated as critical events that contribute to outcome. Close analyses of the interpersonal transactions that constitute these events could have important implications for the conduct of therapy.

5.03.4.2.1 Future directions for research

Programmatic research by Patterson and his colleagues on resistance in parent management training addresses many of the major limitations found in process studies of child-centered therapy, including the explication of a specific process model, the examination of interpersonal exchanges over multiple sessions, and the evaluation of process–outcome relations. Although this work focuses on parental resistance, and not on interactions between therapist and child, these studies constitute a research strategy that could be applied to interactional processes in child therapy. Among the many strengths found in this line of research are (i) the operationalization of a pivotal clinical construct, (ii) the development of a reliable coding system for tracking different types of resistant behavior in therapy, (iii) the systematic analysis of patterns of resistance over the course of therapy, (iv) the investigation of antecedents of resistance, including both client pretreatment characteristics and therapist actions, and (v) the analysis of the impact of resistance on treatment outcome. The approach also sets the stage for the study of therapeutic transactions, that is, patterns of interdependencies between therapist and client behavior over the course of treatment. Because this line of investigation goes beyond the scope of many studies of child therapy process, and could serve as a prototype for investigations in this area, this work will be reviewed in some detail.

As Patterson and Chamberlain (1994) note, resistance to change is a phenomenon acknowledged by virtually all the major therapeutic systems, yet relatively little empirical research has been conducted on this pivotal clinical problem. One difficulty has stemmed from the lack of a consensual definition of resistance and a corresponding method of operationalizing the concept. In many ways, resistance can be understood most simply as the inverse of the collaborative aspect of the therapeutic alliance. High levels of collaboration indicate that the client is working with the therapist on the specified tasks of therapy. Resistance, then, reflects the absence of this collaborative activity. This framework appears to be consistent with the conceptualization presented by Patterson and colleagues. Parent behavior in therapy is conceptualized as either cooperative or resistant. The former reflects a pattern of behavior that follows the direction set by the therapist, whereas the latter involves behavior that is oppositional, helpless, or tangential to the therapeutic task. Based on observations of treatment failures, five types of resistant responses were identified and reliably coded as part of the Client Resistance Coding System (Chamberlain et al., 1984). These included such behaviors as talking over or cutting off the therapist, expressing an unwillingness or an inability to follow the therapist's suggestions, challenging the therapist's qualifications, introducing new topics to shift the session away from the therapist's direction, and not tracking the therapist's verbalizations. Thus, unlike most of the previously reviewed studies, this approach to interpersonal process employed an observational system with well-defined behavioral markers. It is noteworthy that these markers of interpersonal process are most readily identified through parental language behavior. Given developmental differences in language use between children and adolescents, it is not clear if these markers would be as evident in child therapy.

Several studies have indicated that resistant behaviors in parent training sessions can be reliably coded (Chamberlain et al., 1984; Patterson & Forgatch, 1985), and that they cohere as a meaningful index of parental resistance. Correlational analyses suggest that there are two clusters of parental resistance, one characterized by challenging responses and the other by helpless responses, or what Patterson and Chamberlain (1994, p. 59) have dubbed, "I won't" or "I can't" patterns of resistance.

One advantage of conceptualizing resistance at the level of molecular events is that it allows for an analysis of patterns of resistance over the course of a session or across an entire treatment. It was hypothesized that a prototypical pattern of resistance would emerge in successful parent training cases (Chamberlain et al., 1984; Patterson & Forgatch, 1985). Resistance was expected to be low in the initial phase of treatment as the therapist attempts to build rapport and gather information about the presenting problem. Movement into the middle phase of treatment was expected to be marked by a rise in resistance as the therapist focused on parenting strategies and recommended changes in parenting behavior. During the final phase of treatment it was expected that resistance would decline as the therapist focused on consolidation of acquired skills. In essence, an explicit process model, labeled the "struggle hypothesis" (Patterson & Chamberlain, 1994), was formulated and tested.

Research by Chamberlain et al. (1984) confirmed this pattern, with parents showing the highest levels of resistance in the middle phase of treatment. Cases rated as more successful showed the expected decline in resistance between the middle and late phases of treatment. Parents who dropped out of treatment evinced higher levels of initial resistance to therapy than those that continued; however, among those completing therapy, initial levels of resistance were unrelated to ratings of treatment success. It should be noted that an important limitation of this study was the use of therapist ratings of success as the sole index of treatment outcome (although such ratings have subsequently been shown to be related to changes in child behavior). Nevertheless, the results of this study provide the foundation for two important hypotheses. First, the findings suggest that the pattern of resistance over the course of treatment may be a better predictor of treatment outcome than mean levels of resistance. Second, the results suggest that parental resistance is not exclusively the function of individual dispositional differences, but may be closely related to variations in therapist behavior. Both hypotheses represent significant departures from the type of questions typically addressed in studies of child therapy process. The former draws attention to patterns of change and the shape of trajectories over the course of treatment, and the latter underscores the importance of investigating process at the level of client–therapist exchanges where interpersonal interdependencies can be uncovered.

In an effort to understand the impact of therapist behavior on parent resistance, Patterson and Forgatch (1985) examined the covariation in therapist and client reaction sequences. They hypothesized that efforts to produce change would have an unintended "paradoxical" effect on clients by increasing levels of noncompliance. In the first study involving six therapist–client pairs, they predicted that therapist efforts to teach and confront would be associated with the greater conditional likelihood of resistant behavior compared to base rate levels. Conversely, therapist supportive and facilitative behaviors were expected to result in lower conditional probabilities of noncompliance relative to base rate levels. In order to evaluate covariation between therapist and client behavior, it was necessary to develop a therapist behavior coding system to complement the client codes. The Therapist Behavior Code includes seven mutually exclusive categories such as support, teach, and confront. Results indicated that in four of the six pairs, therapists' attempts to teach was associated with significantly higher than base rate levels of resistance, and in six of six pairs, confrontation, described as a "more intrusive effort to re-educate," were associated with higher levels than base rate. Supportive and facilitative therapist behaviors were consistently associated with lower than base rate probabilities of resistant behavior. As Patterson and Forgatch (1985) note, despite the fact that therapist behavior preceded the parent reaction, causality could not be inferred because of the possible operation of an unidentified third variable.

In order to address the causal issue, Patterson and Forgatch (1985) conducted an experimental manipulation of therapist behavior in a second study. Utilizing an ABAB design, they showed that systematic manipulation of therapist "teach" and "confront" behaviors resulted in corresponding changes in client resistant behavior. Increases in teaching and confronting were matched by increases in resistant behavior in B1 and B2, and a reduction of teaching and confronting in A2 produced a return to baseline in resistant behaviors. Taken together these results provide support for the hypothesis that variation in parental resistance is not merely a function of dispositional differences across parents, but is linked to what the therapist does during the session. This is not to say that pretreatment characteristics are unrelated to parental resistance. In fact, Patterson and Chamberlain (1994) report that stress, depression, and parental antisocial behavior contribute to initial levels of maternal resistance even after partialling out indices of social disadvantage. It is noteworthy that changes in level of resistance are not predicted by pretreatment characteristics, instead the pattern of resistance over the course of treatment appears to be determined by interactional processes in sessions.

Finally, evidence indicates that the pattern of resistance over the course of treatment is strongly predictive of outcome (Stoolmiller, Duncan, Bank, & Patterson, 1993). Patterson and Chamberlain (1994, p. 56) hypothesized that the prototypical pattern of resistance in successful cases follows and inverted V function, and have dubbed this pattern the "struggle hypothesis." Cases that show a rise in resistance during the instructional middle phase followed by a decline toward the baseline in the latter phase of treatment were expected to show positive outcomes. Utilizing growth curve analysis, Stoolmiller et al. showed that lack of negative curvature in resistance curves predicted child arrests over a 2 year period following treatment. In contrast, the more conventional approach to assessing process by measuring resistance early and late in treatment and then computing a change score failed to predict child treatment outcome. As Stoolmiller et al. (1993, p. 927) note, "what goes on in the therapy process appears to have better predictive validity than the assessed therapy endpoint or overall change from therapy initiation to therapy termination."

In summary, this line of process research provides a blueprint for future investigations of interpersonal processes in child therapy. Although such studies might examine other process dimensions, for example, patterns of emotion-regulating interactions, emulation of the programmatic character of research on parental resistance would increase the likelihood of useful results.

5.03.4.3 Symbolic Transactions in Child Psychotherapy

Much of what has been said about interpersonal transactions in child psychotherapy applies to symbolic transactions as well. In fact, strictly speaking, the symbolic character of communication processes *per se* suggests that interpersonal and other types of meaningful exchanges in child therapy are properly considered a subtype of symbolic transactions. Clearly, discourse, nonverbal gestures, and play are inherently symbolic, regardless of what their topical focus may be, and regardless of how they may differ in terms of their constitutive communication channel (e.g., verbal vs. nonverbal), their degree of rule-governedness, their type of referentiality (e.g., referring to actual vs. pretend worlds), and their degree of consequentiality (e.g., literal vs. play actions). In brief, child psychotherapy is a form of symbolic interaction, and to understand its processes and how they relate to outcomes, requires an understanding of what humans do most characteristically, namely communicate vis-à-vis symbolic exchange.

Although the above may seem painfully rudimentary, the field of psychotherapy research, child and adult alike, has, in the main, skirted the difficult tasks of studying symbolic processes during the therapeutic hour and of relating them to outcomes, often themselves different types of symbolic processes (e.g., social skills, academic performance, self-presentation, etc.). This is odd indeed if it is true that symbolic construals of self, other, and the world significantly determine conduct, coalitions, and feelings. Who we are and how we adjust may boil down to what we communicate in our ongoing discourses with others. It should come as no surprise that our status as "*Homo symbolicus*" or "*Homo narrans*" exacts such a price, or, rather, confers such an awesome privilege. The history of research on child psychotherapy seems to have avoided dealing systematically with the consequences of this anthropological truism.

At a simpler level, the lack of a systematically developed research tradition on symbolic processes in child psychotherapy is no less surprising. Experiential, psychodynamic, and cognitive–behavioral theories of treatment each stress aspects of verbalization or symbolization (i.e., what is termed "discourse" in the more current idioms) as constitutive of curative processes. According to experiential theory, symbolizing warded-off prereflective experiences, helps to integrate the client's self, or alternatively, reintroduces the client to his or her experience and to the complete sphere of his or her phenomenal world. In early psychodynamic theory, fully and completely describing early trauma in affect-laden language was thought to serve a cathartic function, just as in later psychodynamic theory, redescribing one's autobiographical experience in action language is thought to promote self-transformation and empowerment. In cognitive theory, rescripting event expectations or transforming narrative schemas of important autobiographical episodes corrects faulty causal theories of the world and appraisals of self-worth and blame. Cognitive–behavioral approaches often focus on self-directed language in the form of self-instructions or verbal problem-solving strategies. As central as symbolic processes have been in the theories that have informed child therapy practice, empirical research on them has been peripheral and sporadic.

However, there have been isolated attempts to study symbolic processes in child psychotherapy. These attempts can be conveniently described as exemplifying two very different research paradigms. These can be dubbed the monological and the dialogical paradigms. Basically, the monological paradigm promotes research strategies that tend to excise the individual's or dyad's symbolic communication from the temporal parameters of discourse and situations in which they are embedded in order to characterize therapeutic communication in terms of its internal features. The dialogical paradigm promotes research strategies that tend to contextualize the individual's or dyad's symbolic communication in the temporal flow of discourse and situations in which they are embedded in order to characterize communication in terms of its relational features.

By noting whether a study focuses on an individual's or dyad's symbolic communication (i.e., its speaker scope), and whether it uses monological or dialogical research strategies, a 2 × 2 matrix describing four methods for studying symbolic processes in child psychotherapy is devised. Rudimentary examples of two of these four investigative strategies were contained in the very first study of the process of child therapy. In it, Landisberg and Snyder (1946) reported the frequencies of certain types of child and therapist speech acts. For example, 30% of the utterances in the sessions sampled were therapist nondirective statements. Here, the focus is on an individual, the therapist, and aspects of his discourse have been excerpted from the flow of conversation and tallied in relative isolation from the context in which it had been embedded. These authors also reported dependent relationships between aspects of therapist and client discourse. For example, they reported that therapist reflection of feelings were most often followed by client giving of information or taking some positive action. Here the focus is on the interactive dyad, and aspects of the therapist's and client's discourse are described in relation to each other. The same strategy was employed by Moustakas and Schalock (1955), but they described dependencies running from therapist to child discourse and from child to therapist discourse. The history of research in child and adult symbolic processes in therapy, however, has contained far more studies influenced by the former, monological strategy than the latter, dialogical strategy.

Note that the studies described above are exclusively focused on describing process and relations in it. They do not relate the frequencies of, or the extent of certain types of dependencies between, aspects of therapist or client discourse to outcomes. Truax et al. (1973) provide an example of the use of the monological approach to relate process to outcomes. They reported that children who received the highest levels of therapist-offered relationship conditions evidenced more improvement on a host of outcome measures than children receiving the lowest levels of therapist conditions. This study would seem to support the idea that there is a dose–response relationship between therapist conditions and child outcomes, although the findings are ambiguous insofar as the therapists' behavior could have resulted from variation in child responsiveness (see Russell (1994) for a discussion of this relationship).

The other two cells of the 4 × 4 matrix represent two kinds of hybrids of the monological and dialogical approach. For example, Truax and Wittmer (1973) tabulated the degree to which a certain type of therapist–client exchange occurred across sessions of child treatment, and related these frequencies to outcomes. Basically, the exchange that they tabulated consisted of pairs of child defense–therapist confrontation. The study is focused on aspects of the dyadic exchange (a feature common to the dialogical approach), but exchanges are excerpted from the temporal flow of interactive discourse, and their frequency related to outcomes (a feature common to the monological approach). Interestingly, the authors reported that those clients whose defenses were most often confronted achieved significantly better outcomes than those whose defenses were less often confronted.

In the 1980s and 1990s the other hybrid began to emerge in process studies. For example, Mook (1982a, 1982b) and Russell et al. (1996) applied methods (the P technique, a form of factor analysis applied to within-subject data matrices) that enabled them to describe the underlying structure of covariation of sets of variables used to rate either the therapist's or client's utterances. Here the focus is relational and contextual, as it describes how sets of utterance characteristics (e.g., degrees of information seeking, interpretation, confrontation, empathy) covary over the temporal course of sessions (a feature common to the dialogical approach). In these studies the context is restricted to the corpus of therapist or client utterances, not the interaction between both (a feature common to the monological approach). Together, these studies suggested that therapist participation in treatment discourse is structured around at least two underlying tasks—information seeking alternating with attentive listening, and the application of therapist techniques that help to sustain topical focus across utterances.

The studies reviewed above are minimal instantiations of the four types of process studies defined by crossing methodological strategy (monological vs. dialogical) and speaker scope (one or more dimensions). More sophisticated instantiations have begun to appear. For example, in Shirk and Russell (1996), a study by Estrada, Russell and colleagues is described in which the P technique is used to examine the underlying interactive structure of child therapist and client discourse. Here the focus is on context and relation as incorporated in the P technique, but now both child therapist and child client discourse are entered into the analyses, thus representing the first fully dialogical study undertaken in child therapy. The authors compared high- with low-quality child therapy sessions, and found that the high-quality sessions contained more P-technique factors that indicated systematic conversational exchange between therapist and client across at least two turns of talk than the low-quality sessions.

Obviously, there are other types of studies that can be conducted on symbolic processes in child therapy. For example, Russell et al. (1991) attempted to describe types of therapist discourse taken in their totality. Three types were sufficient to describe the bulk of treatment studies. Therapist discourse tended to be either conversational, instructional, or behavioral as in operant or counterconditioning treatments. The intent of this meta-analytic study was to relate these types of discourse on symbolic tasks such as reading, spelling, and verbal interaction. The authors reported that the effect size associated with conversational discourse was over 10 times as large as that associated with instructional discourse and over four times as large as that associated with behavioral discourse. In addition, there was a relatively strong dose–response relationship between the number of sessions of treatment and the effect size associated with language outcome variables.

The conclusions of Russell et al. (1991, p. 918) to their meta-analysis are worth repeating: (i) "A potentially rich and clinically significant area of child functioning has been only sporadically studied (i.e., only about 20 out of 105 outcome studies contained a language measure)"; (ii) "Ratings or categorization of the *in vivo* therapist and child language interaction are [nearly] uniformly missing"; and (iii) "This domain of functioning seems sensitive to the effects of child treatment, providing an additional, nonreactive dimension for the assessment of outcome." As we have seen, since 1991, there have been both calls for more child process research (Kazdin, 1995) and several attempts to devise and apply dialogically oriented research strategies (e.g., Russell et al., 1996). The field is ripe to more fully plumb the complexities of symbolic interaction in child treatments.

5.03.4.3.1 Future directions for research

Several directions for future research seem worth pursuing. One is suggested by trends in the child process literature itself, and is reinforced by similar but earlier achieved advances in the adult process research. Over the course research since the 1940s, there has been a trend, in child and in adult process research, away from disproportionate reliance on monological research strategies and toward the development of more dialogical research strategies. These developments should continue as we better understand the bi- or multi-directional causality underlying the patterning of human interaction. As suggested in Section 5.03.4.2.1 in interpersonal processes, changes in the patternings of child and therapist discourse may be the best process predictors of treatment progress and outcomes. Second, there has been a dearth of process and outcome measures cut from the same conceptual cloth. Symbolic processes, evident everywhere in human interaction, can provide a rich resource for defining process and outcome variables that share considerable family resemblances. For example, despite the importance of language competence in skillful social behavior, problem-solving, and self-regulation, few studies measure language change, such as pragmatic competence, as an outcome of child treatment. Third, when the symbolic character of child therapy is taken seriously, its study will require familiarization not only with advanced quantitative and qualitative techniques of data analysis, but with theories of discourse and language analysis that have been developed in other disciplines. Thus, we recommend cross-disciplinary training for process researchers. Finally, following developments in the adult process literature, we recommend intensive study of sets of change episodes rather than random samples or whole therapy sessions. Such a focus may enable us to draw a finer bead on the mechanisms responsible for therapeutic change.

5.03.5 THERAPEUTIC TRANSACTIONS AND TREATMENT OUTCOMES

As Orlinsky et al. (1994, p. 270) have observed, the investigation of process–outcome relations is guided by the core question "What is effectively therapeutic about psychotherapy?" Given the relevance of this question for the practice of psychotherapy, one would assume that the investigation of process–outcome relations would represent one of the most prominent strategies among psychotherapy researchers. In fact, in the adult psychotherapy literature there has been rapid growth in this approach to treatment research. In their review of the process–outcome literature, Orlinsky and colleagues uncovered over 2300 findings, with more than half of them appearing since 1985. Studies of the therapeutic relationship alone accounted for nearly 1000 findings. Most importantly, process–outcome investigations have yielded promising results; Orlinsky et al. identified 11 robust process–outcome links, including global therapeutic bond, patient cooperation vs. resistance, and patient expressiveness.

In stark contrast to the adult literature, remarkably few studies of child psychotherapy have examined process–outcome relations. The magnitude of discrepancy cannot be overstated. In their review of 223 child treatment studies, Kazdin et al. (1990) identified only 6 that examined treatment process in relation to outcome! Our own review (Russell & Shirk, in press) revealed some growth in process–outcome research during the 1990s, but even a doubling of the number of studies represents a small effort in absolute terms. Not surprisingly, then, "robust" findings, or, for that matter, replicated findings, remain elusive.

How is the paucity of research on process–outcome relations in child psychotherapy to be accounted for? Surely child clinicians and researchers are no less interested than their adult counterparts in what is "effectively therapeutic." One clue to this remarkable gap can be found in what has been done by child therapy researchers. As Kazdin (1994, p. 577) has noted, much of child therapy research has utilized either a "treatment package strategy" or a "dismantling strategy." In the former, effects of whole treatments are evaluated, and in the latter, treatments are dissected and components are varied across groups. Common to both of these strategies is the assumption that broad technical procedures, for example, social skills training or problem-solving training, constitute the "effectively therapeutic" components of treatment. Thus, by examining the presence or absence of these components in relation to outcome, either by use of a control or dismantling comparison, one attains some perspective on treatment process, at least at a molar level. Although this is a reasonable starting point, the limitations of this perspective are worth mentioning.

First, even if we assume that the active ingredients of therapy are technical procedures—be they problem-solving training or mutual story-telling exchanges—such procedures can be instantiated in treatment in a variety of ways. For example, problem-solving training typically involves some combination of didactic, modeling, and role play activities with varying degrees of emphasis on hypothetical or "live" situations. Moreover, research has shown that the "same" treatment procedure or component delivered in alternative ways can have a differential effect on treatment outcome. For example, Schleser, Meyers, and Cohen (1981) varied the manner in which self-instructional training was presented to children with self-control problems.

In the traditional condition, the therapist provided the child with direct examples of self-instructions, such as, "What is it that I need to do"; in the directed-discovery condition, children were induced to discover basic self-instructions through dialogue with the therapist. For example, the therapist might ask "What is the first thing you need to ask yourself when you start a task?" Variation in this dimension of process, in this case discourse patterns, resulted in differences in skill generalization among more mature children. Although all treated children received the same treatment component, self-instructional training, the manner in which it was presented had an impact on outcome.

Alternatively, other investigators have found that variation in presentation of specific treatment procedures do not produce differential outcomes. Instead, what matters is the quality of the child's involvement with the treatment procedure, regardless of how it is presented. For example, Milos and Reiss (1982) assigned children who evinced high levels of separation anxiety to one of three thematic play conditions: free play, directed play, and modeled play. All three conditions produced comparable reductions in anxiety despite substantial variation in the nature of play interactions, that is, despite differences in the instantiation of thematic play as a treatment technique. However, variation in outcome was related to quality of treated children's play. Children who benefitted most displayed high levels of mastery of oriented play, regardless of technical variations in play interventions. Thus, what was "effectively therapeutic" could not be attributed to specific play techniques but to variations in children's play activity.

The focus on treatment packages or dismantled components of whole therapies restricts the search for effective ingredients of therapy in a second way. As mentioned, these approaches share the assumption that technical procedures are primarily responsible for therapeutic change. At one level of analysis, such an assumption seems to be warranted. Meta-analytic findings suggest that behavioral treatments produce larger treatment effects than nonbehavioral treatments (Weisz et al., 1995), and most certainly these two broad classes of treatment entail substantially different types of technical interventions. However, comparisons of treatments at a more molecular level, for example, comparisons of different types of behavioral treatments such as parent training vs. cognitive-behavioral treatments, do not reveal differential treatment effects. Thus, despite important differences in treatment techniques across subtypes of child behavior therapy, variations in treatment effectiveness are not clearly evident. Such equivalence raises the possibility that other processes which are common across technically diverse treatments could have a significant impact on treatment outcome.

Research on treatment of adult depression is an interesting case in point. Here the central focus has been on comparisons of treatment packages, for example, cognitive-behavioral vs. interpersonal therapy. Despite important differences in component techniques, several treatments appear to be equally effective (Robinson, Berman, & Neimeyer, 1990). Moreover, emerging evidence suggests that other processes, aside from technical procedures, contribute to recovery from depression. For example, analyses of outcomes for depressed adults treated with cognitive-behavioral methods have revealed that therapeutic empathy has a moderate to large effect on recovery, even after controlling for initial level of depression and technical factors (Burns & Nolen-Hoeksema, 1992). Our point is not that relationship processes are the active ingredient of psychotherapy, but rather that such processes are often overlooked when researchers narrowly focus on the evaluation or comparison of treatment packages. As this example suggests, important change processes can be detected by an analysis of process–outcome relations within a well-defined form of therapy. Our understanding of "what is effectively therapeutic" in child therapy will be advanced by broadening the scope of inquiry to include other, "nontechnical" dimensions of therapy process.

5.03.5.1 Promising Directions for Process–Outcome Research

Few studies have actually examined treatment processes in relation to various outcomes, at either the treatment or session level. The absence of findings makes it tempting to turn to the adult process–outcome literature for direction. As Kazdin (1995) has noted, one virtue of such an approach is that continuities and discontinuities between adult and child therapy could be investigated. Alternatively, one could adopt a developmental perspective and consider some of the features of child therapy that represent unique challenges for practicing child clinicians. Thus, analogous to the change events paradigm of process research (Greenberg, 1991), in which predefined change events are examined as an alternative to sampling the full flow of events during sessions, aspects of therapy could be selected because of their developmental significance in child treatment.

One of the most developmentally salient, and at times most problematic, aspects of child therapy process involves the referral process. Children rarely refer themselves for treatment, and often do not acknowledge stress or distress. Consequently, it is likely that children and adolescents will vary considerably in their interest in and motivation for treatment. Variation in motivation could have direct effects on treatment outcome, or could influence outcome indirectly by affecting collaboration with treatment tasks. In one of the few studies of process–outcome relations in child therapy, Braswell et al. (1985) found that verbal markers of active involvement in treatment were predictive of gains in cognitive-behavioral therapy. Thus, one area that merits further investigation is the relation between treatment collaboration/resistance and treatment outcome with children.

Although treatment collaboration/resistance may be related to various child pretreatment characteristics, it is also likely that patterns of therapist–child interaction contribute to treatment involvement. One area that has been ignored by researchers involves the establishment of treatment goals with child patients. Such goals are often defined by parents, teachers, or others who are affected by the child's difficulties. But to the degree that the child is to be an active participant in treatment, a shared definition of a problem (or situation to be changed) may be critical for treatment involvement. The early exchanges that contribute to the definition of goals for therapy represent a developmentally critical aspect of child therapy process, and a therapy event that is likely to vary substantially across children at different developmental levels. Language processes are likely to be pivotal in this aspect of therapy. For example, discrepancies between child and therapist narratives about presenting problems could influence the development of a collaborative treatment relationship.

A related issue involves the role of parents in child therapy. The dependency of children on adult care-givers carries a number of important implications for process–outcome research. First, parents make decisions about initiation and continuation in treatment. There are few consistent findings on factors affecting attrition from child therapy (Armbruster & Kazdin, 1994), but research indicates that a substantial portion of parents elect not to continue after an initial evaluation (Weisz, Weiss, & Langmeyer, 1987). One possibility is that continuation in child therapy may be predicted from the strength of alliance the therapist forms, not just with the child, but with the parents as well.

If this is the case, collateral parent consultation that keeps the parents informed and involved may be critical for effective child treatment. Relatively little is known about the type of parental involvement that could facilitate child treatment.

A second issue involves the role of ongoing parent–child interactions in relation to in-session interactions. For example, therapists may attempt to facilitate emotion expression in the context of therapy, only to have such efforts counteracted by sanctions against expressive behavior in the family. From a treatment perspective, collateral work with the family would be clearly indicated. From a process perspective, the link between in-session processes and treatment outcomes is likely to be moderated by parental acceptance and support of therapeutic activities. It is possible that treatment acceptability (Kazdin, French, & Sherick, 1981) will exert a significant influence on the strength of process–outcome relations. Similarly, variation in parental participation in programs aimed at generalization of in-session activities will undoubtedly influence process–outcome relations. Thus, the study of process–outcome relations in child therapy will need to be contextualized in order to account for the impact of facilitative or corrosive parent–child interactions.

In summary, process–outcome relations in child therapy remains a relatively uncharted area. Although various aspects of process have been investigated in child therapy (cf. Shirk & Russell, 1996), remarkably few studies have related these processes to treatment outcomes. Consequently, this area of investigation has yet to find a meaningful starting point. It is our recommendation that investigators consider developmentally salient process issues, such as interactions aimed at defining mutual treatment goals, as they begin to examine process–outcome relations.

5.03.6 CONCLUSIONS

A review of child therapy process research reveals some promising leads but many substantial gaps in the existing literature. Most striking is the dearth of research linking treatment processes with treatment outcomes. Linkages among referral processes, treatment preparations, treatment transactions, and outcomes are virtually unexplored. Although one might expect such studies to be the centerpiece of process research, their absence undermines our ability to answer the core question: "What is effectively therapeutic about child psychotherapy?" It is the contention that progress in the field hinges on a shift in research focus to an examination of therapeutic processes in relation to treatment outcomes. In order for such a shift to be fruitful, however, a number of changes must occur in the conduct of child process research.

First, the notion of therapy process implies a temporal dimension. Static operationalizations of process fail to capture the flow of therapy. "One-shot" assessments of critical processes, such as the therapeutic alliance, are not as likely to contribute to our understanding treatment process as patterns of processes across sessions or whole treatments. Furthermore, the investigation of transactions, that is, sequences of exchange that occur over time, should complement detailed characterizations of process. Such research holds promise for identifying specific patterns of interaction that constitute broad constructs such as the alliance or treatment involvement. Furthermore, the identification of such patterns could provide useful information to practicing child clinicians.

Second, process research itself has had a restricted focus. Most studies have examined the activities of one individual in isolation. Child process research must redirect attention to therapeutic exchanges and contingencies between child and therapist behavior. Ironically, few studies have examined interaction *per se*, the hallmark of therapeutic process. Instead, frequencies of individual behavior are typically tabulated without reference to dependencies between behaviors. Alternatively, few efforts have been made to examine process at the level of the dyad. Just as a secure attachment describes a type of relationship, shifting the unit of analysis to the dyad could reveal process characteristics that are not captured at the individual level. Finally, relatively little attention has been directed toward the broader social context in which child therapy process is embedded. For example, the contribution of parents and peers to children's involvement in therapy is relatively unexplored.

Finally, most child process research has been descriptive in nature, and atheoretical in focus. Part of the problem stems from the fact that child process research has evolved in isolation from the field of developmental psychopathology (Shirk & Russell, 1996). Treatment processes attain relevance to the degree to which they are specifically related to pathogenic processes. Thus, child process research cannot be dissociated from investigations of pathogenic mechanisms that contribute to child dysfunction. Understanding of pathogenic mechanisms will guide the search for change processes in child psychotherapy.

5.04.1 INTRODUCTION

After decades of child treatment guided by psychology's grand theories and rarely subjected to rigorous test, we are moving into an era in which claims of success may have little credence in the absence of outcome research. The forces ushering in this new era are both scientific and fiscal. On the scientific front, both the American Psychological Association (APA) and the American Psychiatric Association are moving toward identification of research-based principles and practices for intervention with adults, adolescents, and children (see, e.g., Task Force, 1995). On the fiscal front, the advent of managed care has brought increased attention to the issue of outcomes, as companies seek to limit the cost of care. In the area of child and adolescent treatment, the body of relevant evidence is now growing fast, with more than 300 child and adolescent treatment outcome studies already published. This chapter summarizes some of the major findings of these studies, and then becomes critical, noting limitations of the available evidence and suggesting issues that will need attention in the future. Throughout the chapter, the term "children" is used to refer to the age period from early childhood through adolescence, except where it is necessary to draw a distinction between children and adolescents.

5.04.2 SOCIAL, DEVELOPMENTAL, AND CULTURAL CONTEXT OF CHILD ASSESSMENT AND THERAPY

Although clinical work with children bears obvious similarities to work with adults, some important differences warrant emphasis. First, because children rarely perceive themselves as "disturbed" or as candidates for therapy, most referrals for treatment, up until late adolescence, tend to be made by parents, teachers, or other adults. These adults may thus be construed as "clients" in the sense that they commission the therapy, pay for it, and identify some or all of the goals the therapist is to pursue. Children may or may not participate in identifying target problems or setting treatment goals, and even when they participate, the adult input may be weighted more heavily. With therapy commissioned by adults, and its goals heavily influenced by adults, it is understandable that children may enter the process with little motivation for treatment or personal change, or with different objectives than those shared by the adults involved.

Given marked developmental differences in the self-awareness, psychological mindedness, and expressive ability of their clientele, child therapists must rely heavily on adults for information about the youngsters they treat, and this can present problems of several types. First, parents' and teachers' reports may be inaccurate, based on distorted samples of child behavior, influenced by their own adult agendas, calculated to conceal their own failings as parents (including neglect or abuse), or even biased by their own pathologies (see e.g., Kazdin, 1989); and levels of agreement among different adult informants reporting on the same child tend to be low (Achenbach, McConaughy, & Howell, 1987). Bias and distortion aside, adult reports of child behavior and adult identification of referral concerns are both apt to reflect the values, practices, and social ideals of their cultural reference group (see Weisz, McCarty, Eastman, Chaiyasit, & Suwanlert, 1997; Weisz et al., 1988; Weisz & Weiss, 1991).

Finally, children tend to be captives of their externally engineered environments to a much greater extent than do adults; one consequence may be that the "pathology" the child therapist treats may reside as much in a disturbed environment from which the child cannot escape as in the child himself or herself. This may limit the impact of interventions involving the child as solo or primary participant, and it may argue for involvement of others from the child's social context, but such significant others are not always willing or cooperative. So, in a number of ways, the child therapist faces challenges that are rather different from those confronted by one who treats only adults.

5.04.3 PREVALENCE OF CHILD DYSFUNCTION AND CHILD TREATMENT

Notwithstanding the difficulties of child assessment and child treatment, both practices are widespread, in both clinical practice and research contexts. Systematic efforts at assessment in the general population suggest that large numbers of children suffer from significant levels of disturbance, at least as defined within the current taxonomic systems. Epidemiologic studies in the late 1980s (summarized by Costello, 1989) indicated that at least 17% of children in the general population met criteria for at least one diagnosis in the *Diagnostic and statistical manual of mental disorders, Third Edition* (*DSM-III*; American Psychiatric Association, 1980); preliminary findings point to higher prevalence rates for the most recent edition of the diagnostic manual (*DSM-IV*). Of course, these rates of formal diagnosis overlook the many children who have very significant problems that fall short of full diagnosability, but may well need help, nonetheless.

Each year, many troubled children receive intervention in the form of child psychotherapy, but precise figures on the extent and cost are difficult to find. Figures for the late 1980s indicated that about 2.5 million American children received treatment each year (Office of Technology Assessment, 1986), and that the annual cost was more than $1.5 billion (Institute of Medicine, 1989). These figures are apt to be underestimates, given the likelihood that much child treatment is either not formally labeled "psychotherapy" (e.g., counseling in school) or not formally reported to government agencies (e.g., private practice paid out of pocket). Of course, much has changed since the 1980s, with some forces (e.g., the rise of managed care, general reductions in duration of inpatient stays) discouraging growth, but other forces (e.g., increased public awareness, legislated entitlements for handicapped children) encouraging growth, so updated statistics on use and costs are clearly needed.

5.04.4 TYPES OF TREATMENT AND PROBLEMS TARGETED IN TREATMENT

The most common types of treatment used with children, and the most common child conditions addressed in treatment, are described in other chapters of this volume, but a few facts germane to outcome assessment warrant emphasis here. As Kazdin (1988) noted, there are more than 230 named psychotherapies, but most of these have not been subjected to controlled tests of outcome. In general, outcome research with children has focused on a distinct subset of the treatments that bears little apparent relation to frequency of use in clinical practice. Among the psychological interventions (i.e., excluding pharmacological therapies), psychodynamic and family therapies are among the most widely practiced by clinicians but among the least studied by outcome researchers. By contrast, behavioral and cognitive-behavioral interventions are emphasized in outcome research to a degree that far exceeds their use in clinical practice.

There is somewhat closer correspondence between practice patterns and the outcome research with respect to problems targeted in treatment, but the correspondence is less than perfect. Most of the types of child problems encompassed in Chapters 13–27, this volume have been the focus of both clinical attention and some outcome research, although much of the research has addressed specific problems or clusters of problems rather than full-blown diagnostic categories; this may have been appropriate, given periodic changes in the taxonomy, but late 1990s trends incline toward formal diagnostic assessment of children in clinical trials. Of the diagnostic categories noted in this volume, the problems associated with conduct disorder (and oppositional defiant disorder), attention deficit hyperactivity disorder (ADHD), anxiety disorders (including particularly specific phobias), and possibly somatoform disorder (especially chronic headache) have been emphasized in clinical trials research, whereas other problems frequently treated by practitioners are less evident in clinical trials research.

5.04.5 WHO CARES ABOUT OUTCOMES OF CHILD TREATMENT?

Stakeholders with an interest in the outcome of child treatment are numerous. The treated child's need for help, not to mention his or her investment of time and energy in the process of treatment, arguably makes the child the major stakeholder. Add parents and other family members who seek relief for the child, and also frequently for the family. Teachers' interests, as well, may include both concern for the child and for the classroom of which the child is a part. Those who finance the child's treatment (e.g., family members, government agencies, insurance carriers) have a clear stake. And finally, the therapists, clinic staff, administrators, and others in the "provider" community have a clear interest in the outcomes of the care in which they invest their careers. All these parties to the process of treatment have a clear stake in the question, "How effective is child psychotherapy?"

5.04.6 APPROACHES TO ASSESSING TREATMENT EFFECTS

This question can be answered via several different methods, a few of which need to be noted here. The most widely recognized is the clinical trial, an outcome study in which the post-treatment adjustment of a group of children who received a candidate intervention is compared with that of one or more control groups who did not. It is these clinical trials studies that are most frequently pooled in reviews and meta-analyses (see below), and that thus constitute most of the evidence discussed in this chapter. However, in circumstances where all the children in a target group must receive an active treatment, multiple baseline designs, ABAB (sometimes called "reversal") designs, and simultaneous/alternating treatment designs are useful. Such approaches characterize much of the treatment research with ADHD youngsters (see, e.g., Pelham et al., 1993), for example, and they are frequently used in cases where an entire classroom is the target of an intervention (e.g., Wurtele & Drabman, 1984). These non-clinical trials designs can also be applied to cases (sometimes involving rare conditions) where only one or two children will be treated (e.g., McGrath, Dorsett, Calhoun, & Drabman, 1988; Tarnowski, Rosen, McGrath, & Drabman, 1987). These alternative outcome assessment designs have generated a rich body of data on treatment effects, data that await an enterprising reviewer. For now, though, the focus is on the clinical trials research, which has been reviewed rather thoroughly in the form of several meta-analyses, as described below.

5.04.7 POOLING OUTCOME STUDIES VIA META-ANALYSIS: METHODS AND ISSUES

Research findings on psychotherapy effects can be pooled via a technique called meta-analysis (see Mann, 1990; Smith, Glass, & Miller, 1980; but see also critiques, e.g., by Wilson, 1985). The building block of meta-analyses is the effect size (ES) statistic. The ES is an index of the size and direction of treatment effects. For typical clinical trials studies, ES is the difference between the post-treatment mean on an outcome measure for the treated group vs. the corresponding control group mean, with the difference divided by the SD of the outcome measure. Figure 1 is a guide to interpreting ES values. As the figure indicates, positive ES values indicate treatment benefit, and negative values indicate a harmful effect. Each ES value corresponds to a percentile standing of the average treated child on the outcome measure(s) if that child were placed in the control group after treatment; for example, an ES of 0.9 indicates that the average treated child scored better after treatment than 82% of the control group. As an aid to interpretation, Cohen's (1992) guidelines suggest that an ES of 0.20 may be considered a "small" effect, 0.50 a "medium" effect, and 0.80 a "large" effect. By averaging across the outcome measures used, a meta-analyst may compute a single mean ES for each study (or each treatment group) in the collection being reviewed. This permits computation of an overall mean ES for the entire collection of studies; it also permits comparison of mean ES across studies differing in potentially important ways: for example, in the type of therapy employed, the target problem being treated, or the age or gender of the children involved.

Methods have been proposed for assessing the quality of studies considered for inclusion in meta-analyses (see, e.g., Chalmers et al., 1981), but most meta-analysts in the psychotherapy research area have aimed for rather broad, representative collections of outcome studies, accepting a range of methods, provided that certain basic standards of experimental design are satisfied. Weiss and Weisz (1990) carried out a meta-analysis to assess the extent to which methodological variations in child outcome studies might be associated with differences in ES. Findings indicated that nine commonly noted internal and external validity factors (e.g., whether subjects were randomly assigned to groups, whether subjects were analog cases or clinical cases who would have been treated independently of the study) together accounted for 7% of the variance in ES, over a sample of 105 outcome studies. They also found no evidence that inclusion of methodologically weaker studies in meta-analyses has led to overestimates of ES; on the contrary, increased experimental rigor in the studies they sampled was generally associated with *larger* ES. Thus, it is possible that the most inclusive meta-analyses may tend to underestimate the true effect of therapy, compared to meta-analyses that apply strict methodological criteria to candidate studies.

Meta-analysts must make myriad decisions as they carry out their work, and many of these decisions have an impact on the ultimate ES values that will emerge. For example, decisions must be made about whether to (i) compute ES by dividing the treatment–control group difference by standard deviation (SD) of the control group or of the pooled control plus treatment groups; (ii) compute an average ES across all outcome measures within a study or keep these separate for overall ES calculation; (iii) combine ES computation across various treatment conditions, compute separate ES values for each treatment group in a study, or use some amalgam of these two approaches; and (iv) weight all studies equally or adjust ES according

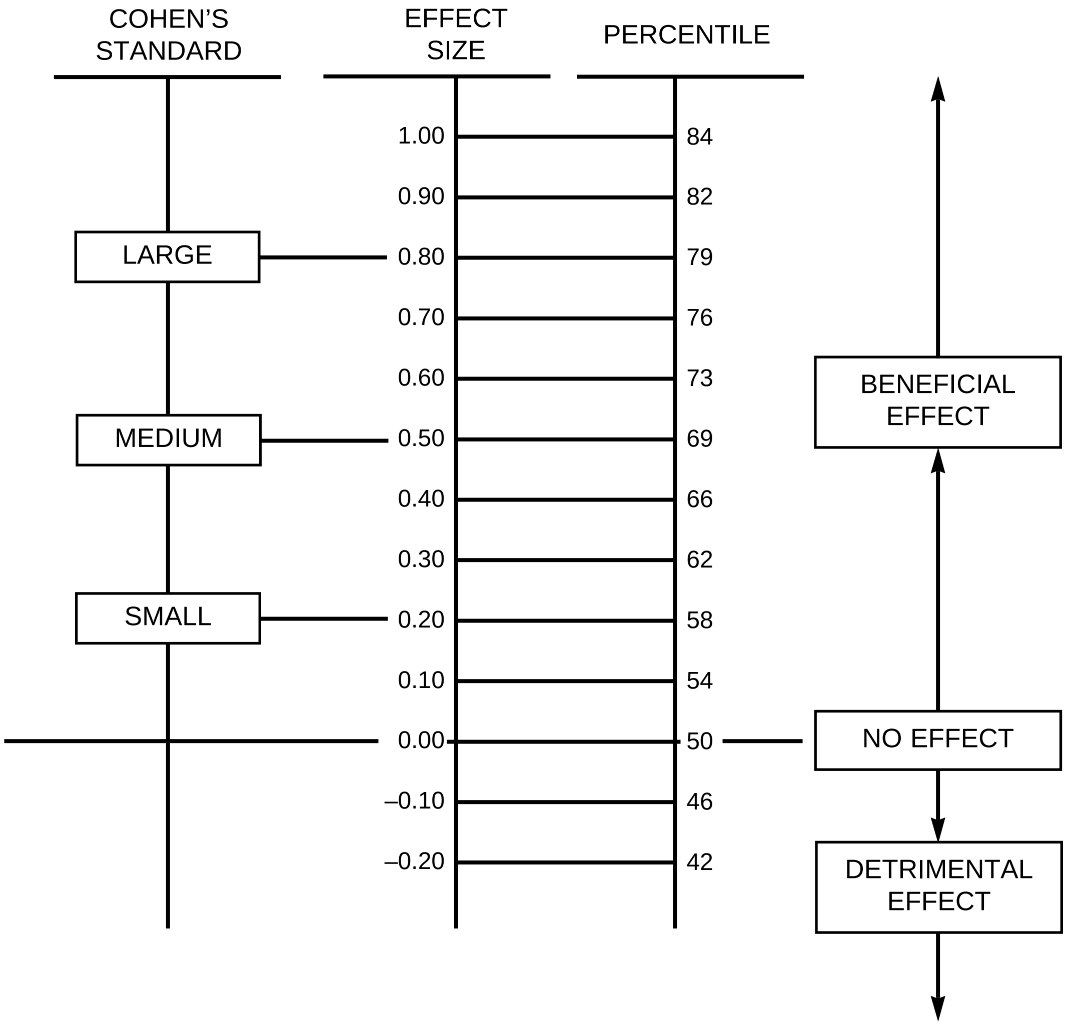

Figure 1 An aid to interpreting effect size (ES) statistics. ("Bridging the gap between laboratory and clinic in child and adolescent psychotherapy," by J. R. Weisz, G. R. Donenberg, S. S. Han, and B. Weiss, 1995, *Journal of Consulting and Clinical Psychology, 63,* pp. 688–701. Copyright 1995 by the American Psychological Association. Reprinted with permission.)

to sample size, ES variance, or some other leveling factor (for discussion of these and other decision-making issues, see Weisz & Weiss, 1993; Weisz, Weiss, Han, Granger, & Morton, 1995). Because scores of such decisions are made in any meta-analysis, it is essentially impossible that any two teams working independently will conduct their work in exactly the same way.

This fact, of course, highlights the need for caution in comparing findings across different meta-analyses, and thus in reading the results reported below. Differences in ES means across different meta-analyses may be influenced in part by differences in the ways the respective meta-analysts compiled studies, pooled them, computed ES, or averaged ES within or across studies. To assist the reader in interpreting the meta-analytic findings reported below, the four issues noted in the preceding paragraph have been addressed in the following way: For each meta-analysis, only *exceptions* to the most common approach to each issue are noted. That is, unless otherwise noted, the meta-analysis being described involved the following modal procedures for child meta-analysis: (i) ES was calculated by dividing the treatment–control group difference by SD of the pooled control plus treatment groups; (ii) within each study, ES values are averaged across all outcome measures; (iii) within each study, separate ES means are maintained for each treatment vs. control group comparison; and (iv) ES values reported are unadjusted.

5.04.8 FINDINGS FROM META-ANALYSES

This section considers some of the findings of meta-analytic reviews, first covering overall effect sizes found in broad-based analyses, then noting findings of specially focused analyses, and finally identifying some heuristically useful findings on therapy, therapist, and child factors related to the magnitude of treatment effect.

5.04.8.1 Findings of Broad-based Meta-analyses

To date, there have been at least four broad-based child psychotherapy meta-analyses: that is, meta-analyses imposing minimal limits on treated problems or types of intervention to be included. In all, these four meta-analyses encompass more than 300 separate treatment outcome studies. In the earliest of these, Casey and Berman (1985) surveyed those outcome studies published between 1952 and 1983 that involved children aged 12 and younger. Mean ES was 0.71 for those studies that included treatment–control comparisons; in percentile terms, the average treated child scored better after treatment than 76% of control group children, averaging across outcome measures. In a second meta-analysis, Weisz, Weiss, Alicke, and Klotz (1987) reviewed outcome studies published between 1952 and 1983, with children aged 4–18. Mean ES (computed using control group SD) was 0.79; after treatment, the average treated child was at the 79th percentile of control group peers.

In a third broad-based meta-analysis, Kazdin, Bass, Ayers, and Rodgers (1990) included studies published between 1970 and 1988, with youngsters aged 4–18. Kazdin et al. included multiple types of studies, but for the subset that compared treatment groups and no-treatment control groups, mean ES was 0.88; the average treated child scored higher after treatment than 81% of the no-treatment comparison group. For studies comparing treatment groups to active control groups, mean ES was 0.77, indicating that the average treated child was functioning better, post-treatment, than 78% of the control group.

In the fourth broad-based meta-analysis, Weisz, Weiss, et al. (1995) included studies published between 1967 and 1993, involving children aged 2–18. ES values were calculated using control group SD (for rationale, see Weisz, Weiss, et al., p. 455), and using the conservative procedure of collapsing across treatment groups up to the level of analysis; for example, except for analyses comparing different types of therapy, ES values were averaged across treatment groups within a study. An overall mean ES of 0.71 indicated that, after treatment, the average treated child scored higher on the outcome measures than 76% of control group children. When ES values were weighted by the inverse of their variance, the overall ES mean dropped to 0.54. (For more detailed descriptions of the procedures and findings of these broad-based meta-analyses, see Weisz & Weiss, 1993.)

The findings of these four broad-based meta-analyses show rather consistent beneficial treatment effects; ES values ranged from 0.71 to 0.84 (0.84 is an estimated overall mean for the treatment–control comparison studies in Kazdin et al., 1990), near Cohen's (1988) "large effect" index of 0.80. (Note, though, that the Weisz, Weiss, et al. (1995) finding noted in the preceding paragraph suggest that true population ES means, adjusting for heterogeneity of variance, may be closer to "medium" effects.) For comparative purposes, Figure 2 shows findings of the four child meta-analyses together with findings of two of frequently cited meta-analyses with older groups, that is, Smith and Glass's (1977) meta-analysis of primarily adult psychotherapy outcome studies, and Shapiro and Shapiro's (1982) meta-analysis of exclusively adult outcome studies. As the figure indicates, effects found in the child meta-analyses fall roughly within the range of effects found in these two adult meta-analyses.

5.04.8.2 Findings of Specially Focused Meta-analyses

Beyond the findings of these broad-based meta-analyses, there is a good deal to be learned from focused meta-analyses addressing rather specific questions about child treatment effects. Three such projects have dealt with cognitive-behavioral therapy in particular. For example, Baer and Nietzel (1991), reviewing 36 outcome studies, found quite positive treatment effects for cognitive and/or cognitive-behavioral treatments addressing child impulsivity. Mean ES was 0.90, calculated with control group ES, pooling only across similar outcome measures, and without weighting; the mean dropped to 0.77 when ES was weighted by study sample size. Dush, Hirt, and Schroeder (1989) focused on 48 child outcome studies using the cognitive-behavioral technique of self-statement modification; pooling outcome measures to produce one ES mean per study, Dush et al. found a mean ES of 0.47. Durlak, Fuhrman, and

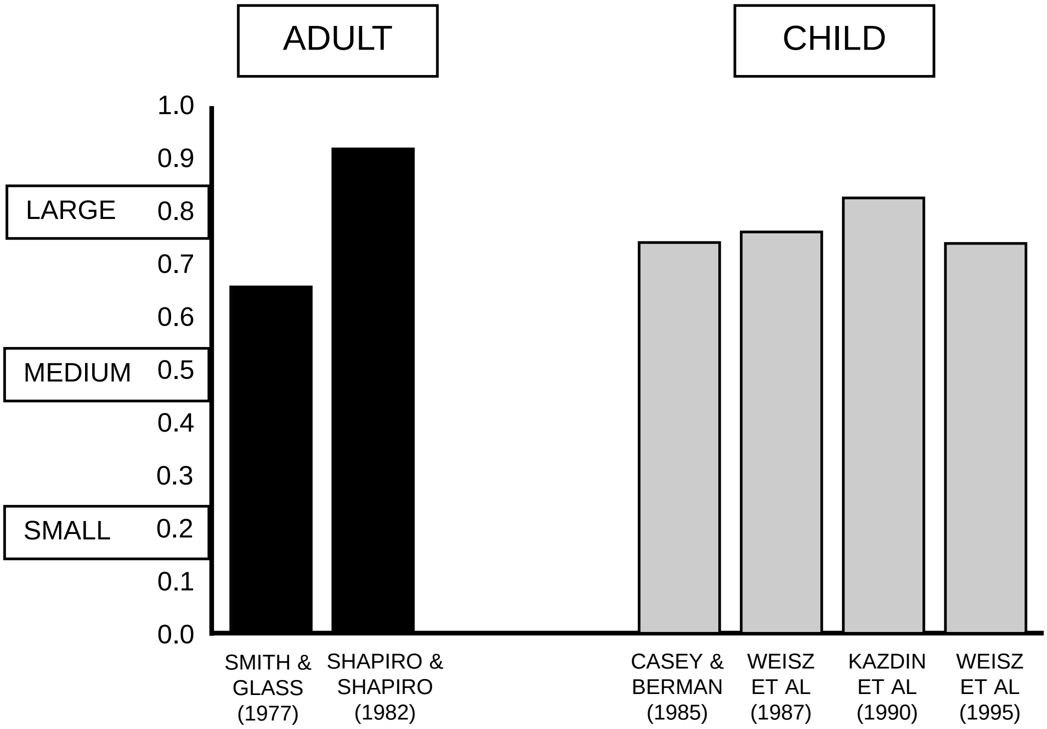

Figure 2 Mean effect sizes found in meta-analyses of psychotherapy outcome studies with adults and children. ("Bridging the gap between laboratory and clinic in child and adolescent psychotherapy," by J. R. Weisz, G. R. Donenberg, S. S. Han, & B. Weiss, 1995, *Journal of Consulting and Clinical Psychology*, *63*, pp. 688–701. Copyright 1995 by the American Psychological Association. Reprinted with permission.)

Lampman (1991) surveyed 64 studies of cognitive-behavioral treatment with children, applied across a range of target problems. With ES values pooled within studies to produce a single mean ES per study, and weighting by study sample size, Durlak et al. found a mean ES of 0.56, averaging across all age levels. However, as these authors had hypothesized, the mean was considerably higher for older children (0.92 for ages 11–13) than for younger groups (0.57 for ages 5–7, 0.55 for ages 7–11), suggesting that these cognitively oriented treatments may be a better fit to more cognitively mature youth. In a worrisome finding, Durlak et al. noted a negligible correlation (–0.22) between cognitive changes and behavioral changes, thus raising an important question about a key assumption underlying cognitive-behavioral therapy, namely the notion that the technique brings about behavioral change by inducing cognitive change.

Family therapy has been the subject of two meta-analyses. Hazelrigg, Cooper, and Borduin (1987) reviewed 20 family therapy outcome studies, averaging across multiple effects within studies to produce a single mean ES per study. For the seven studies that met their methodological criteria and included outcome measures of family interaction, the mean ES, weighted by study sample size, was 0.45; for the six methodologically appropriate studies that included behavior ratings of individual children in the family, the weighted mean ES was 0.50. Thus, although the number of relevant family therapy studies was small, Hazelrigg's meta-analysis pointed to beneficial effects. In another meta-analysis, Shadish et al. (1993) surveyed 101 studies involving family therapy (plus another 62 studies of marital therapy). Aggregating multiple ES values within studies to the study level, and weighting studies by the inverse of their sampling variance, Shadish et al. found a mean ES of 0.47 for the 44 family therapy studies that included treatment–control group comparisons. For comparison with the Hazelrigg et al. findings, Shadish also computed weighted ES means separately, for measures of family interaction and for ratings of individual family members' behavior; the family interaction ES was 0.31 (vs. 0.45 in Hazelrigg et al.), and the behavior rating ES was 0.66 (vs. 0.50 in Hazelrigg et al.).

Three additional meta-analyses illustrate the range of questions that can be addressed via this method of synthesis. Prout and DeMartino's (1986) meta-analysis, focused on psychotherapy in school settings, based ES computation on SD of the control groups, and pooled ES values only across groups of similar outcome measures; thus, 33 studies, involving 52 treatment–control comparisons, generated 119 individual ES values that were included in the analysis. The resulting (unadjusted) ES mean was 0.58. Russell, Greenwald, and Shirk (1991), computing ES using the control group SD in their meta-analysis of 18 child outcome studies, found that treatment was associated with significant improvement in children's language proficiency (unadjusted $ES = 0.39$). Treatments that emphasized spontaneous verbal interaction produced the biggest language improvements, compared to those involving more structured and constrained procedures. Finally, Saile, Burgmeier, and Schmidt (1988) carried out a meta-analysis of 75 controlled outcome studies involving psychological preparation of children for medical (including dental) procedures, ranging from minor procedures such as injections and drawing blood samples to such serious procedures as lumbar punctures. ES was computed using SD of study control groups. The overall mean ES was modest, 0.44, but there was considerable variation across types of intervention; for example, mean ES was only 0.22 for procedures in the "minor" category (e.g., injections) but 1.50 for procedures classified as "major" (e.g., cardiac catheterization). This report by Saile et al. (1988), like the article by Prout and DeMartino (1986), reminds us that a good deal of psychotherapy with children takes place in settings outside a therapist's office, and that evidence is needed on outcomes in these less traditional settings just as for office-based treatment.

5.04.8.3 Therapy, Therapist, and Child Factors Related to the Magnitude of Treatment Effects

In addition to overall mean ES values, meta-analyses can yield estimates of the impact of various therapy, therapist, and client factors on treatment outcome. Such estimates need to be interpreted with caution because of the confounding among factors (e.g., treatments and treated problems) that is common in meta-analyses. Some of the confounding can be addressed via statistical control and testing of interaction effects (see, e.g., Weisz et al., 1987; Weisz, Weiss, et al., 1995), although this is only a partial solution. In the two meta-analyses from the author's lab (Weisz et al., 1987; Weisz, Weiss, et al., 1995), studies involving behavioral treatments (e.g., behavioral contracting, modeling, cognitive-behavioral therapy) were found to produce larger effects than studies using nonbehavioral treatments (e.g., insight-oriented therapy, client-centered counseling). The Casey–Berman (1985) meta-analyses showed the same effect, at $p = 0.06$; Kazdin et al. (1990) did not make this comparison; general superiority of behavioral methods was also reported in Prout and DeMartino's (1986) meta-analysis of school-based treatment studies, and in meta-analyses not specific to children, by Nicholson and Berman (1983) and Shadish et al. (1993). By contrast meta-analyses have generally not found treatment outcomes to differ reliably for different types of treated problems (e.g., internalizing vs. externalizing; for one exception, see Casey & Berman, 1985, pp. 392–393).

The relation between age and treatment outcome has varied across meta-analyses. However, the meta-analysis involving the most recent collection of studies (Weisz, Weiss, et al., 1995) found mean ES to be larger for adolescents than for children. This main effect was qualified by the age and gender interaction depicted in Figure 3; for samples of predominantly or exclusively adolescent girls, mean ES was twice as large as for adolescent boys and for children of both genders. Of course, adolescent girls may be more likely to be treated for internalizing problems than are younger children or adolescent boys; but we found no reliable difference in mean ES for internalizing vs. externalizing problems, nor was the age and gender interaction in Figure 3 qualified by type of treated problem (internalizing vs. externalizing), type of treatment (behavioral vs. nonbehavioral), or level of therapist training (professional vs. clinical trainee vs. paraprofessional). Perhaps there is something about the 1990s generation of treatments reflected in this 1995 meta-analytic collection of studies that fits the characteristics and needs of adolescent girls particularly well, but one is left to speculate about what that elusive quality may be.

Three additional findings illustrate other potentially useful contributions of meta-analytic data. First, meta-analysis can be used to assess the holding power of intervention effects. Findings in both the meta-analyses (Weisz et al., 1987; Weisz, Weiss, et al., 1995) indicated that treatment effects assessed immediately after treatment are quite similar to effects measured at follow-up assessments, which average about six months after treatment termination. This suggests that treatment benefits tend to be durable, at least within typical follow-up time frames (for similar conclusions derived from different kinds of outcome studies, see Durlak et al. (1991); Nicholson & Berman (1983); Shadish et al. (1993)). Second, individually administered treatments have tended to show larger effects than group treatments, although not always significantly so (see Casey & Berman, 1985;

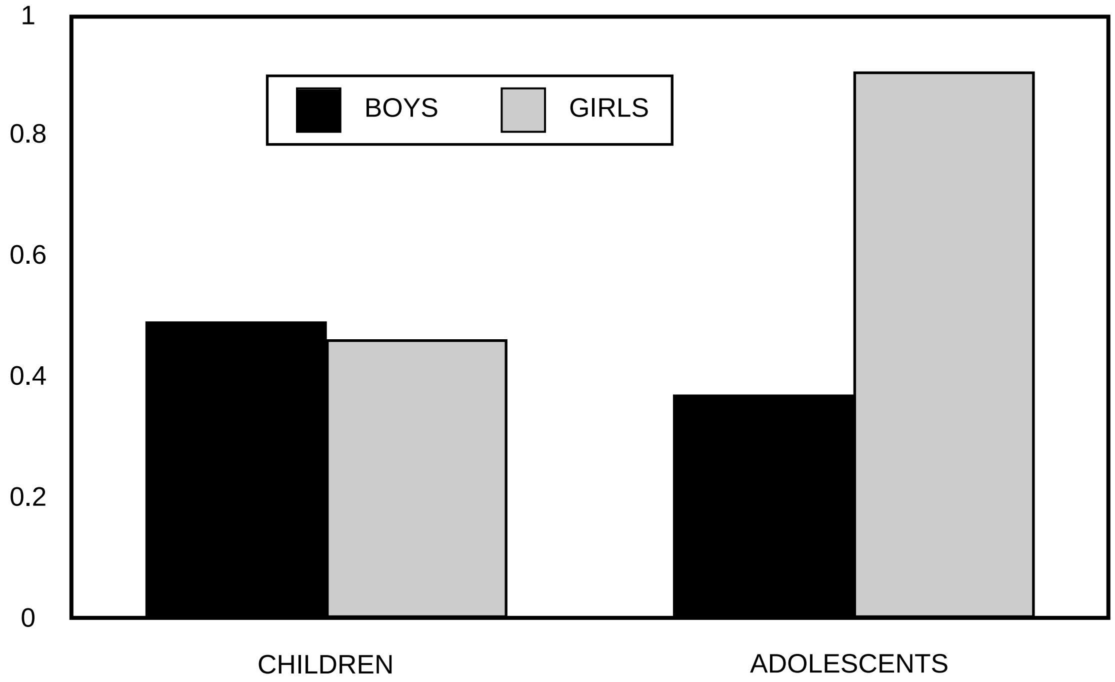

Figure 3 Mean effect size for samples of predominantly male and female children (11 years of age and younger) and adolescents (12 years and older). ("Effects of psychotherapy with children and adolescents revisited: A meta-analysis of treatment outcome studies," by J. R. Weisz, B. Weiss, S. S. Han, D. A. Granger, and T. Morton, 1995, *Psychological Bulletin, 117,* pp. 450–468. Copyright 1995 by the American Psychological Association. Reprinted with permission.)

Russell et al., 1991; Weisz et al., 1987; Weisz, Weiss, et al., 1995), and there is at least one exception in the area of cognitive-behavioral treatments for impulsivity (Baer & Nietzel, 1991).

A third finding (from Weisz, Weiss, et al., 1995) concerns the specificity of treatment effects. Obviously, children differ markedly from one another in the particular problems they manifest, and various therapies differ in the problems they are designed to address, but do these individual differences actually influence treatment outcome? Some (e.g., Frank, 1973) have proposed that psychotherapy has "nonspecific" effects, for example, helping people with diverse problems through such general means as promoting a feeling of being understood or encouraging an expectancy of relief. An alternative view is that therapies help in specific ways, having their strongest influence on the specific problems they are designed to address.

This controversy was addressed in Weisz, Weiss, et al. (1995) with a test of whether effects were larger for the specific problem domains targeted by a treatment than for other, more incidental domains. For example, we asked whether a treatment for anxiety produced bigger changes in anxiety than in related but more peripheral problems such as depression. Across multiple comparisons like these, we found that ES means were about twice as large for the specific problems addressed in treatment as for related problems that were not specifically addressed. This suggests that these psychotherapies were not merely producing global or nonspecific good feelings that influence diverse outcomes equally; instead, the treatments appeared to have rather precise, focused effects consistent with the particular objectives of the therapy.

In sum, evidence from broad-based meta-analyses of child psychotherapy outcome studies points to positive, problem-specific, and durable effects of mental health interventions for a variety of child problems. Clearly, child psychotherapy research is generating a number of encouraging findings. On the other hand, several conceptual and methodological issues require a good deal of attention in the future. Attention is now focused on some of these issues, and related suggestions for future research.

5.04.9 EXTERNAL VALIDITY AND RESEARCH THERAPY VS. CLINIC THERAPY

One issue is that of external validity. Most of the 300-plus studies in the meta-analyses reviewed above (particularly the recent and behavioral studies) involved participants, interventions, and/or treatment conditions that are actually not very representative of conventional clinical practice with referred children. In many of the studies, (i) children were recruited for treatment, were not actual clinic cases, and had lower levels of dysfunction than most referred children; (ii) child samples were homogenous, with therapy addressing only one or two focal problems (e.g., a specific phobia); (iii) therapists received considerable pretherapy training and session-by-session supervision in the specific intervention techniques they would use; and/or (iv) the therapy involved adherence to those specific techniques. In addition, (v) therapy was often highly structured and guided by a manual, with therapists monitored for fidelity to the treatment program.

These features of the outcome studies, although they are useful experimentally, tend to coalesce around an abstract category that the author and his colleagues (e.g., Weisz, Weiss, & Donenberg, 1992) have called research therapy, which we distinguish from conventional clinic therapy. Table 1 summarizes some illustrative differences between the two therapy genres. The two are best thought of as two poles of a multidimensional continuum; certainly no single feature shown in the table under Research therapy is present in all clinical trials studies, and few of the individual features listed under Clinic therapy are true of all clinic-based treatment. However, differences between child therapy in clinics and child therapy in clinical trials outcome studies are common enough for it to be reasonable to ask whether the positive outcomes generated in the research therapy studies, and summarized in the meta-analyses above, are representative of the outcomes achieved in actual clinical practice with children.

Table 1 Some common characteristics of research therapy and clinic therapy.

Research therapy	*Clinic therapy*
Recruited cases (less severe, study volunteers)	Clinic-referred cases (more severe, some coerced into treatment)
Homogeneous groups	Heterogeneous groups
Narrow or single-problem focus	Broad, multiproblem focus
Treatment in lab, school settings	Treatment in clinic, hospital settings
Researchers as therapists	Professional career therapists
Very small caseloads	Very large caseloads
Heavy pretherapy preparation for therapists	Little/light pretherapy preparation for therapists
Preplanned, highly-structured treatment (manualized)	Flexible, adjustable treatment (no treatment manual)
Monitoring of therapist behavior	Little monitoring of therapist behavior
Behavioral methods (e.g., operant, respondent, modeling, CBT)	Nonbehavioral methods (e.g., psychodynamic, eclectic

Weiss, 1995, *Journal of Consulting and Clinical Psychology*, *63*, pp. 688–701. Copyright 1995 by the American Psychological Association. Reprinted with permission.)

5.04.9.1 Evidence on the Effects of Clinic Therapy

To address this question, the author and colleagues carried out a search (described in Weisz, Donenberg, Han, & Weiss, 1995) for published outcome studies that focused on what might fairly be called clinic therapy. Studies were sought that involved (i) treatment of clinic-referred (i.e., not "analog" or recruited) youngsters, (ii) treatment in service-oriented clinics or clinical agencies, not in research settings (e.g., not university labs or public schools), (iii) therapy carried out by practicing clinicians (as opposed to trained research assistants), and (iv) therapy that was part of the usual service provided by the clinic, not a special treatment program designed specifically for research. It was required that the studies involve direct comparison between youngsters who received treatment and a control group receiving no treatment or a placebo intervention.

One of the first lessons learned was this: clinic studies that meet the criteria outlined above are very rare. The author and colleagues had carried out one such study (Weisz & Weiss, 1989), but found only eight others that fit the criteria (Ashcroft, 1971; De Fries, Jenkins, & Williams, 1964; Jacob, Magnussen, & Kemler, 1972; Lehrman, Sirluck, Black, & Glick, 1949; Levitt, Beiser, & Robertson, 1959; Shepherd, Oppenheim, & Mitchell, 1966; Smyrnios & Kirkby, 1993; Witmer & Keller, 1942), and these spanned 50 years, most having been published many years earlier. Although the studies all compared treatment and control groups, they used several different methodologies (for details, see Weisz, Donenberg, Han, & Kauneckis, 1995). To facilitate comparison of these nine studies with the meta-analytic findings reviewed above, an ES or ES estimate was computed for each of the nine studies (using, where necessary, estimation procedures described by Smith et al., 1980, and Glass, McGaw, & Smith, 1981). As shown in Figure 4, ES ranged from –0.40 to +0.29, with mean ES for the nine clinic studies (0.01) falling well below the mean ES of the four broad-based meta-analyses discussed earlier (0.77). Although these nine clinic studies provide only a very limited sample of clinical treatment, the disappointing findings certainly raise the possibility that outcomes of conventional clinical therapy may be less positive than the outcomes of research therapy.

It is useful to consider these findings in the light of evidence on "continuum of care" or "system of care" programs for children, that is, efforts to link multiple conventional mental health services for children with the services frequently organized and coordinated by individual child case managers (see, e.g., Stroul & Friedman, 1986). In one of the most recent (1995) and most ambitious of these efforts (see, Bickman, 1996; Bickman et al., 1995), the US Army spent $80 million to provide a continuum-of-care program for children of military personnel at Fort Bragg, NC, and to test the program's cost-effectiveness relative to more typical fragmented services in a matched comparison site. Considerable evidence indicates that the Fort Bragg program did produce a rich array of well-integrated mental health services (see details in Bickman et al., 1995). Indeed, the program was judged by the APA's section on Child Clinical Psychology and Division of Child, Youth, and Family Services Joint Task Force to be

> the most comprehensive program to date, integrating many of the approaches demonstrated by other service programs . . . integrated and flexibly constructed, yet comprehensive, [with] services available to be adapted to meet the needs of children and their families, rather than a simplistic application of a single approach. (Roberts, 1994, p. 215)

There is good evidence (see Bickman et al., 1995) that the program produced improved access to treatment, but it also cost more than services in the comparison site: $7777 per treated child vs. $4904. Unfortunately, despite the increased access to care and despite the increased costs, the Fort Bragg program produced clinical outcomes that were no better than those in the matched comparison site. Fort Bragg children received more mental health intervention, at greater cost, but their mental health outcomes were not improved by the increase.

Similar null findings have emerged from other studies designed to alter, link, or improve delivery of conventional clinical services (see, e.g., Evans et al., 1994; Lehman, Postrado, Roth, McNary, & Goldman, 1994). A number of alternative interpretations of such findings may be plausible, but one possible interpretation is that the various treatments that are linked and coordinated in these continua of care are simply not very effective, individually or in combination. In fact, Bickman and colleagues (Bickman, 1996; Bickman et al., 1995) appear to favor such an interpretation, after having tested the major rival interpretations they could identify. Put simply, there is no indication that the individual interventions employed in these various continua of care have been shown to be effective in clinical trials (or approximations thereto); thus, it is possible that the various interventions are simply not very helpful to children. An array of ineffective services may not produce much true benefit regardless of the extent to which they are multiplied, coordinated, or organized into continua of care.

So, the evidence reviewed on representative clinical interventions with children points to two conclusions: Evidence on conventional clinical treatments provides little support for their effectiveness; evidence on effects of integrating conventional interventions into systems of care also shows little evidence of treatment benefit.

5.04.9.2 Research Challenges

The findings on clinic- and community-based interventions suggest useful directions for future research. First, it is clear that we need more information on outcomes of treatment under representative clinical conditions. Research in this genre—known as "effectiveness" studies, as opposed to controlled "efficacy" studies—is difficult but certainly not impossible, as the nine studies cited in Figure 4 demonstrate (for a discussion of the pros and cons of various relevant methods, see Weisz & Weiss, 1993). The base of information on psychotherapy effects in public clinics is quite thin, but the situation is even worse for other treatment contexts. As best as can be determined there is, up to 1997, no methodologically sound treatment–control study of outcomes in such now-common treatment configurations as individual and group private practice and health

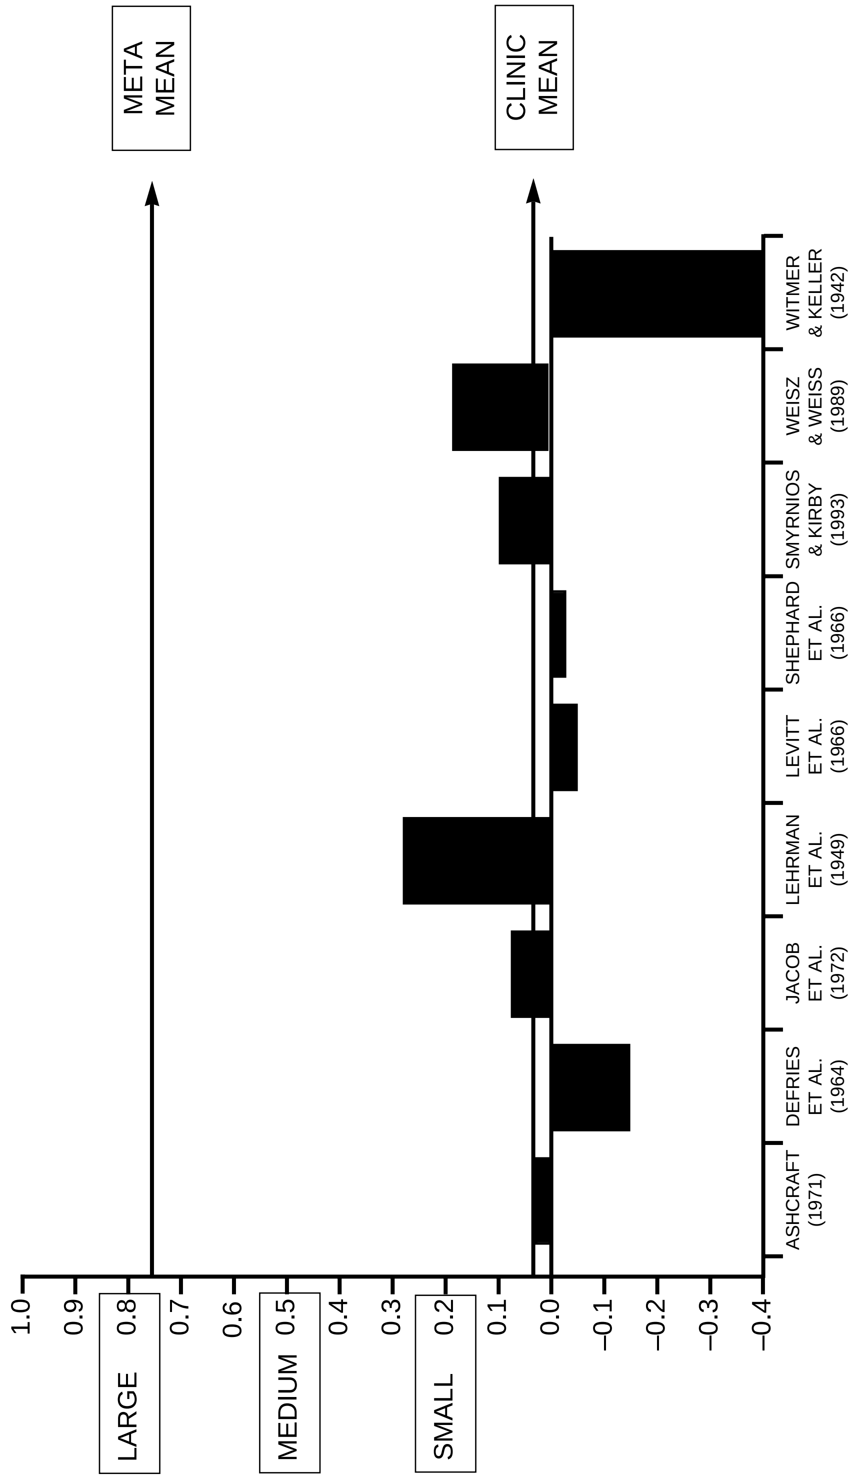

Figure 4 Estimated effect sizes for nine studies of clinic-based psychotherapy with children and adolescents. Horizontal arrows show mean effect size for four broad-based meta-analyses of laboratory outcome studies (top), and averaging across the nine clinic-based studies (bottom). ("Bridging the gap between laboratory and clinic in child and adolescent psychotherapy," by J. R. Weisz, G. R. Donenberg, S. S. Han, and B. Weiss, 1995, *Journal of Consulting and Clinical Psychology*, *63,* pp. 688–701. Copyright 1995 by the American Psychological Association. Reprinted with permission.)

maintenance organized (HMOs). Evidence is needed on outcomes in these forms of practice to ascertain how practice effects in the 1990s compare to outcomes of laboratory interventions. Moreover, without such information, there is a lack of baseline data for tracking the impact of potentially critical changes in service patterns, such as the introduction of managed care, or implementation of empirically validated treatments (discussed below).

Second, assuming that further research continues to show poor effects of conventional clinical treatment, it is necessary to identify factors that explain why therapy in clinical trials experiments produces strong positive effects and therapy in clinics does not. The author and colleague have made two attempts to address this issue (Weisz, Donenberg, Han, & Kauneckis, 1995; Weisz, Donenberg, Han, & Weiss, 1995). In both, they used meta-analytic data sets to investigate which, if any, of the factors that distinguish research therapy from clinic therapy (e.g., of those shown in Table 1) might account for significant variance in outcome. In a 1995 effort, using the most complete sample (Weisz, Donenberg, Han, & Weiss, 1995), we examined eight potentially relevant factors (from the list shown in Table 1), and two were found that were significantly related to treatment outcome: First, behavioral treatments were associated with better outcomes than nonbehavioral treatments, and second, analog cases showed better outcomes than clinic-referred children. The first finding suggests the possibility that clinic-based treatment might be more effective if more behavioral treatments were used; nonbehavioral interventions are widely used in clinical practice, and it appears that behavioral therapies are not the first choice of most practitioners (see Kazdin, Siegel, & Bass, 1990). The second finding suggests that even lab-tested treatment methods may be less successful with truly clinic-referred children than with the less disturbed children who are so often the subjects in lab studies. This issue is discussed in the next section.

5.04.10 EXPORTABILITY OF EMPIRICALLY SUPPORTED TREATMENTS

At first, the array of findings presented above might appear to argue for incorporation of empirically supported treatments into clinical practice. The logic would be this: (i) evidence from clinical trials research with children shows positive effects of numerous treatments; (ii) evidence on conventional treatments in clinical settings shows generally modest-to-negligible effects; thus, (iii) to generate beneficial effects in clinical settings, one should identify those treatments that have been supported in clinical trials and export them to clinics. This logic may be appealing to many who support the efforts of the APA Task Forces (adult and child, see Task Force, 1995) on empirically validated treatments, and the logic may prove to be valid in the long term. However, it may be a mistake to assume that the empirically supported treatments are ready for export. The subjects and treatment conditions involved in tests of the empirically supported treatments tend to differ so much from everyday clinic cases and conditions that it is not clear how workable or effective the supported treatments will be in clinical settings. At the very least, the differences mean that treatment developers cannot simply drop their manuals at the clinic doorstep and assume that beneficial treatment effects will follow.

Table 1 offers several reasons for concern. As one example, the fact that empirically supported treatments have most often been supported with recruited or analog samples rather than referred children may be important. Indeed, in the analysis described above (Weisz, Donenberg, Han, & Weiss, 1995, p. 695) mean ES in even the clinical trials research was found to be significantly lower for studies using clinic-referred children than for those using analog samples. This raises a question as to whether treatments supported in clinical trials with subclinical samples recruited from schools would be equally effective with seriously disturbed children referred to clinics. As a second example, clinical trials studies frequently focus on homogeneous groups, selected for the presence of one or two target problems, and with exclusionary criteria eliminating children who have additional unwanted problems. One cannot be sure that treatments supported with such samples will be equally effective with the heterogeneous groups of multiproblem children frequently seen in clinical practice. As a third example from Table 1, the simple fact that most empirically supported treatments are behavioral (including cognitive-behavioral) may make them difficult to implement in clinics where most of the therapists are strongly psychodynamic, or are unfamiliar with, or even hostile toward, the behavioral perspective.

Beyond the issues suggested by Table 1, numerous practical problems arise. A simple example concerns the number of sessions needed to produce beneficial effects. The author's research in child mental health clinics (Weisz & Weiss, 1989; Weisz, 1996), has found that the average outpatient receives 5–10 sessions. By contrast, most of the manuals used to guide empirically supported treatments require more than a dozen sessions, and these are typically devoted to a single focal problem. Given the specificity of most manuals, children referred for three or four major problems may well be candidates for three or four manuals, each requiring more than 12 sessions. In an era of managed care in the private sector and modest capitated budgets in the public sector, strict session limits are apt to be the rule rather than the exception. Thus, it is fair to ask whether the kinds of manualized treatments that now prevail in the empirical literature can be made to work in clinics with prevailing session limits.

Before manualized treatments derived from the empirical literature are implemented in clinics and clinical training programs, a new genre of treatment outcome research may be needed that involves taking empirically supported treatments out of the laboratories where they were developed and studying them in the crucible of clinical practice. The purpose would be to find out what modifications are needed to make the treatments effective with the clientele, and the real-life constraints, of clinical practice. Several investigators have taken steps in this direction, for example, by treating truly disturbed children in university-based lab clinics (see, e.g., Kendall, 1994; Lovaas, 1987). However, more extensive attempts may be needed to incorporate lab-tested treatments into actual clinical practice, and test their effects, before it can be known just how exportable the experimentally derived treatments are, and what changes will be needed to make them work with seriously disturbed children.

5.04.11 CHILD PSYCHOTHERAPY AND DEVELOPMENTAL PSYCHOLOGY

A third issue that needs attention is the relative isolation of child psychotherapy research from the base of theory and evidence on human development. Despite clear overlap in their populations of interest, and despite their shared emphasis on the study of change, research on developmental psychology and on child psychotherapy have remained surprisingly separate, insular enterprises. Saile et al. (1988) have expressed a similar concern regarding treatments designed to prepare children for medical procedures. In introductions to journal articles on the various child treatments, it is surprisingly unusual to see either theories or empirical findings of developmental psychology cited as a basis for the treatment program. The Results sections of treatment outcome articles are frequently notable for relative inattention to developmental factors (even age!) that may relate to treatment effects.

One cause of this state of affairs may be the very success these relatively adevelopmental treatment efforts have had in producing positive effects. Such success may foster confidence that one is on the right track, and may thus undermine motivation to seek input from other subdisciplines. But treatment effects, although positive in most studies, might well be improved through closer ties to the study of development. Treatment benefit might well be enhanced to the extent that treatments fit developmental characteristics of the treated individuals; a knowledge of relevant developmental literature should enhance treatment planners' capacity to produce a good fit, and thus to test this notion.

In addition to treatment planning, developmental concerns may be relevant to outcome assessment. Because outcome research provides much of the feedback needed to guide the development and refinement of treatment procedures, outcome researchers may need to consider ways to attune such research to developmental questions, so as to stimulate clinical–developmental cross-pollination. Accordingly, this section addresses developmental issues that bear on both child treatment planning and outcome assessment.

5.04.11.1 Age

Most outcome researchers report the age range and mean for their samples, but few assess the potential moderating effect of age. Indeed, the Kazdin et al. (1990) survey of 223 child treatment outcome studies showed that only 7% examined any child, family, and therapist variables in relation to outcome. Age is one of the most easily accessible child characteristics, and within-study assessment of its moderating effects could be useful heuristically, generating promising developmental hypotheses. Broad-based meta-analyses like those described earlier can address the general relation between sample age and outcome, across studies; but this pooled approach lacks the precision and control of within-study analyses, or even more narrowly focused meta-analyses, such as Durlak et al.'s (1991) meta-analysis of cognitive-behavioral therapy outcome studies, discussed earlier. The Durlak et al. findings suggest the potential importance of testing for a moderating role of age in each individual outcome study. On the other hand, it must also be noted that the age variable is, at best, a rough summary index of multiple, diverse developmental factors—cognitive, social, and contextual—each warranting attention in its own right.

5.04.11.2 Cognitions About the Therapy Process and the Role of the Therapist

Adult clients frequently begin treatment with some understanding of the nature and purpose of psychotherapy and its purpose, and some sense of the therapist's role. Children, by contrast, may have little awareness of what therapy is, what a therapist does, or what their relationship with the therapist should be. The concepts children at various developmental levels apply to the process, the therapist, and the relationship, are apt to reflect their cognitive developmental level, in interaction with their previous relevant experience, which will differ markedly from one child to another. Our field needs basic inquiry into children's cognitions about these concepts, each of which could well influence their response to treatment and their ultimate treatment outcome.

5.04.11.3 Ability to "Decenter"

Piaget (e.g., 1929, 1962) wrote extensively about the development of "decentration," the ability to detach from one's own point of view and perceive objects or events from an alternate perspective. Early work on this theme dealt with visual perception, but the notion was eventually extended to social contexts and the ability to recognize the perspective of others on activities, events, and even oneself. A limited ability to decenter may set limits on the impact of treatments (e.g., cognitive-behavioral, psychodynamic) that involve role-playing or other efforts to help children see events, conditions, and even themselves from the perspective of others. Accordingly, research on this cognitive ability as it relates to child therapy could shed new light on how children respond to various perspective-taking intervention techniques.

5.04.11.4 Language Ability

Developmental variations in ability to encode and decode language may set limits on the success of therapy, particularly when it relies heavily on verbal interaction. Low level encoding skills may limit a child's ability to convey thoughts and feelings to the therapist, and thus limit the therapist's ability to tailor interventions to the child's inner state. As a simple example, both cognitive-behavioral and psychodynamic treatments for anxiety may require young clients to describe their anxious state in terms of both physiological arousal (e.g., "I feel tense, and I have a knot in my stomach") and psychological state (e.g., "It feels like everyone is staring at me; if I make a mistake, they'll think I'm stupid"). Children who cannot generate such descriptions may not be able to help their therapist understand their anxious states fully enough to design appropriate interventions.

Limited ability to decode therapist comments may also be a problem, limiting how helpful those comments actually can be. Highly scripted, manual-driven therapies that are language-laden may fall outside the range of young clients' capabilities, thus limiting the impact of treatment. Assessment of children's language skills would facilitate detection of such problems.

Finally, considerable research, dating to the work of Piaget (1955/1923) and Vygotsky (1962/1934), points to developmental differences in the ability to use "private speech" or "inner speech" to inhibit or guide behavior (see also Kohlberg, Yaeger, & Hjertholm, 1968; and Zivin, 1979). Piaget and Vygotsky made different predictions about the developmental course of this phenomenon, and subsequent evidence has been equivocal and dependent on the specific type of inner speech involved (see, e.g., Meichenbaum & Goodman, 1979). However, it seems clear that developmental differences in the use of language to guide behavior may well foster differences in responsiveness to those therapies that stress language as a means of self-control. In cognitive-behavioral therapy, for example, children are taught to use "self-talk" to make themselves less impulsive, less anxious, less depressed, less aggressive, and/or more prosocial. Use of self-talk in these ways assumes a well-developed connection between language and action, an assumption that may need to be tested in child outcome research.

5.04.11.5 Comprehension of Concepts or "Lessons" of the Treatment Program

One cognitive phenomenon that cries out for attention in child psychotherapy research is the child's understanding of the conceptual content and central principles of the therapy program. Many child therapies are, in part, educational programs. For example, some treatment programs for depression are designed to teach children the basic components of depression, plus strategies for alleviating depressed mood; and some programs for anxiety try to teach the building blocks of anxiety (e.g., fear, physiological arousal, habitual avoidance, relief that rewards the avoidance), plus specific techniques for promoting exposure to the feared situation. Are there developmental differences in children's acquisition of these concepts and skills, and might such differences influence treatment outcome? For most child therapies, there is too little relevant evidence to provide an empirically respectable answer. Indeed, one of the most striking limitations of research in this field is the infrequency with which outcome researchers test which "lessons" of their treatment were actually learned. Beyond the value of such information for assessing goodness-of-fit between a treatment program to children at different developmental levels, the information would facilitate assessment of the extent to which grasping the various concepts and lessons is associated with clinical improvement.

5.04.11.6 Abstract Reasoning

Certain kinds of abstract thinking, including hypothetico-deductive reasoning, are consolidated in formal operations, typically in adolescence (Piaget, 1970). Yet some treatment programs for preadolescent children appear to require considerable abstract reasoning. For example, some social skills training programs ask children to generate hypothetical stressful social situations, think of various ways they might respond, envision ways that others might respond to their response, and imagine various possible outcomes of the hypothetical interactions that might ensue. As another example, some therapies for depression require movement from concrete instances to abstract categories when they try to teach children to recognize categories of depressogenic thinking such as overgeneralization and catastrophizing (see examples in Cicchetti, Rogosch, & Toth, in press). Developmentally sensitive investigators could help guide treatment developers, by assessing the extent to which children at various developmental levels can master such seemingly abstract reasoning.

5.04.11.7 Organization and the Orthogenetic Principle

The developmental theorist Heinz Werner (1957) proposed an *orthogenetic principle*, the notion that

> wherever development occurs it proceeds from a state of relative globality and lack of differentiation to a state of increasing differentiation, articulation, and hierarchic integration. (p. 126)

This principle overlaps partly with Piaget's (1970) concept of organization, the notion that the developing system integrates cognitive building blocks into an operating structure. In Piaget's view (supported by evidence), even memories of past experience can be reorganized to integrate such experience with newly developed cognitive structures. One implication of these two principles for child treatment researchers is that some of the skills and information taught in a treatment program may be integrated into the developing child's cognitive system over the course of later development, not necessarily within the time frame of the typical child outcome study.

The implications of this notion could be profound. Perhaps, instead of construing child treatment as a direct induction of change, treatment programs should be seen as perturbations planted in the fertile soil of the individual's developing system and destined to interact with that system over time to produce structural changes in the ways the individual processes and responds to experience. Because the nature and timing of this interactive, unfolding process might be strongly influenced by the natural pace of development, our thinking about the objectives and the timing of outcome assessment might also need to be re-examined. Instead of focusing on proximal outcomes induced by their treatment programs alone and seen at the end of those 8–24 week programs, treatment researchers might focus on therapeutic-developmental exchanges, some effects of which might not be measurable until months or even years after treatment termination. Extending outcome research beyond the traditional follow-up periods (which are now rarely longer than six to nine months) might permit detection of slow-blooming changes or "sleeper effects," as the child's developing system integrates the lessons of therapy with other developmental inputs. Of course, extending follow-up assessments would also help researchers detect a falling off of treatment benefit over time, when that occurs.

5.04.11.8 Looking to the Future

This brief sampling of developmental issues suggests that there is much work to be done. Breaking down the traditional insularity of child psychotherapy research and developmental research, though difficult, may be useful to both enterprises. Benefits for those who study child psychotherapy may include richer and more fully informed models of child dysfunction, readiness for treatment, and intervention-to-child fit, and an expanded picture of how outcome assessment may be conducted and employed in the process of treatment development.

5.04.12 RELATION BETWEEN PROCESS AND OUTCOME

A fourth issue that needs attention is the relation between therapy process and outcome.

In Chapter 3, this volume, Stephen Shirk and Robert Russell describe the state of process research in the child area; the present chapter considers a few basic notions relevant to outcome assessment. The most general point concerns the importance of assessing process in relation to outcome. In the absence of process information, broadly construed, information about treatment outcomes is of limited value. When treatment works well, we need to know what processes were involved, so we can repeat them; and when treatment falls, we need to know what to stop doing. Relatively few child outcome studies provide clear measures of the "active ingredients" of their treatments. The typical clinical trial in the child area provides a rather global comparison of a control group to a treatment program involving multiple techniques. Significant global group differences at post-treatment and follow-up are indeed important elements of treatment validation, and for cost-effectiveness probably the most useful first step in treatment development. However, the lack of specificity regarding which elements of the treatment are producing which aspects of client change has led to calls for a more fine-grained analysis of the processes of child psychotherapy that mediate and/or moderate treatment outcome (Kendall & Morris, 1991; Kazdin, 1989), and other aspects of the therapeutic process deserve attention as well. Kazdin et al. (1990) reported that a fourth of their sample of 223 outcome studies varied some therapy components across groups, and only 2% evaluated outcome in relation to treatment processes; this suggests that there is room for growth in research on what factors over the course of the therapy process actually influence change. There are at least four ways of construing such research, each potentially useful.

5.04.12.1 Components of Treatment

In cases where well-replicated effects show a composite treatment program to be effective, a logical next step is to test the effects of various components of the program, in combinations that make sense theoretically and logically. At least two variations on this theme are well-recognized in the field. A dismantling approach involves breaking a program down into components and varying these across groups; an additive approach involves progressive addition of new components, or combining two or more treatments into one. In the Kazdin et al. (1990) analysis of 223 child treatment outcome studies, 26% involved the first approach, to some extent, and 19% involved the second approach. If these numbers seem surprisingly large, it should be borne in mind that 60% of the Kazdin and co-workers' sample of studies involved comparison of two or more treatments, not necessarily with a no treatment or active control group. Nonetheless, the data suggests that research involving "unpacking" specific treatment components is underway in the child area.

5.04.12.2 Therapist Behavior

A second aspect of therapy process that deserves attention is the behavior and style of the therapist, independent of the specific components of an outline or manual. For example, a good deal of research has focused on therapist directness in communication with clients. In a series of studies, Patterson and his colleagues have noted that therapists' direct instructions to parents of antisocial children to change their parenting style are frequently met with noncompliance in session and resistance to change outside sessions (e.g., Patterson & Chamberlain, 1994; Patterson & Forgatch, 1985). On the other hand, Truax and Wittmer (1973) found evidence that directness by the therapist may have positive effects in confronting defense mechanisms in child therapy. As the findings of these two investigative teams suggest, any one aspect of therapist style or behavior may have differential effects depending on the content and objectives of the treatment; and, of course, therapist style may well interact with client style and personality to shape the ultimate effects. Despite the complexity of the task, and the infinite array of therapist style and behavior dimensions that might be addressed, research on this theme may be well worth the investment of time and intellectual resources it will require. Of all the research discussed in this chapter, it is among the most relevant to the task of training future therapists.

5.04.12.3 Child and Family Behavior

A third dimension of process that requires attention is the behavior of treated children and their families over the course of therapy. Research on this theme is illustrated by the work of Braswell, Kendall, Braith, Carey, and Vye (1985) and Gorin (1993) indicating that positive treatment outcomes are associated with clients' active participation in therapy. Causality is difficult to nail down in such research, and it is certainly possible that such client behavior as active participation may be either a cause of the ultimate treatment benefit, a signal that the treatment is resonating with the client and producing change, or both. But, causality aside, the identification of child and family behavior during therapy that can predict ultimate outcome can, in principle, provide a much-needed tool for therapists: a means of determining whether the treatment is working or not, and thus whether adjustments are needed, before the entire intervention program has ended.

5.04.12.4 Therapeutic Relationship

The therapeutic relationship, or working alliance, has been construed as involving two interrelated parts: the client's positive emotional connection to the therapist, and a shared conceptualization between the client and therapist of the tasks and goals of therapy (Bordin, 1979). In the adult literature, development of a therapeutic relationship has emerged as a particularly significant process correlate of positive outcome in several studies (Horowitz, Marmar, Weiss, DeWitt, & Rosenbaum, 1984; Luborsky, Crits-Christoph, Mintz, & Auerbach, 1988). Shirk and Saiz (1992) have argued that this process variable may be an even more significant contributor to outcome for children due to the "involuntary client" status of many children at the beginning of therapy, the nonverbal nature of many forms of client-centered and play therapy for children, and the social deficits that are hypothesized to be central in the development and maintenance of many serious child problems (e.g., aggression).

Child process researchers have studied the therapeutic relationship in play therapy (Howe & Silvern, 1981; Truax, Altmann, Wright, & Mitchell, 1973), family therapy (Friedlander, Wildman, Heatherington, & Skowron, 1994; Pinsoff & Catherall, 1986), individual psychodynamic therapy (Shirk & Saiz, 1992), cognitive-behavioral treatment (Kendall, 1994), child behavior therapy (Motta & Lynch, 1990; Motta & Tobin, 1992), and parent training (Webster-Stratton & Herbert, 1993). However, unlike the consistently positive findings in the adult process literature relating the working alliance to therapeutic success, evidence from child psychotherapy has been mixed, with Shirk & Saiz (1992) reporting positive associations between their measures of the therapeutic relationship and outcome in child psychodynamic psychotherapy, and both Kendall (1994) and Motta (Motta & Lynch, 1990; Motta & Tobin, 1992) finding no significant association between relationship quality and outcome with cognitive-behavioral treatment for anxiety and behavioral therapy for learning and disruptive behavior problems, respectively. The lack of agreement across studies is difficult to interpret, given the study-to-study differences in the way therapeutic relationship is assessed. The field needs a well-validated set of measures for assessing the relationship. Developing such measures for child therapy will be a challenging task. Among the difficulties confronted, two are particularly notable: (i) the complexity of the relationship concepts involved relative to the limited verbal and conceptual facility of many of the children who will be the targets of the assessment; and (ii) the need to encompass not only the child–therapist dyad, but also the parents and possibly additional family members, whose relationship to therapist and child may be critical to the success of treatment.

5.04.13 CHILD AND FAMILY ETHNICITY AND CULTURE

A fifth issue is that of culture and ethnicity in relation to child treatments. In the great majority of child outcome studies, the samples appear to be predominantly Caucasian, although authors have frequently failed to be explicit about sample composition. In the Kazdin et al. (1990) survey of 223 child outcome studies, 80% failed to identify the ethnic composition of their sample. While mere reporting of the relevant numbers is rare, actual tests of ethnicity as a moderator of outcome are even rarer. Some have suggested that treatments tested primarily with mainstream samples may not necessarily be optimal for troubled members of ethnic minority groups (Gibbs & Huang, 1989; Rogler, Malgady, Costantino, & Blumenthal, 1987; Spurlock, 1985; Sue, 1977; Tharp, 1991). The treatments may not, for example, take into account the language, values, customs, child-rearing traditions, expectancies for child and parent behavior, and distinctive stressors and resources associated with different cultural groups. In the treatment setting, such cultural factors may lead to miscommunication and misunderstanding between the therapist and the client and family, thus increasing the likelihood of premature termination and poor treatment outcome (Ho, 1992; Sue & Zane, 1987). Tharp (1991) has also suggested that even the therapy modality requires attention, and that family and group interventions may be more appropriate than individual treatment for many minority youth, and more likely, as well, to generate information for the therapist on cultural issues relevant to the child, family, and community.

The literature on culture and psychotherapy is rich in recommendations for how to treat specific ethnic groups, but poor in controlled empirical assessment on these issues, with most recommendations based on anecdotal and experiential reports (see Gibbs & Huang, 1989; Ho, 1992). The array of hypotheses now available should provide fertile ground for experimentation in the future. For the present, though, a modest base of evidence is available to suggest trends that bear further study. Weisz, Huey, and Weersing (1996) identified 19 treatment outcome studies (most found in the meta-analytic collections from Weisz et al., 1987 and Weisz, Weiss, et al., 1995) in which the majority of the sample were ethnic minority children or families. A few of the findings of these studies are considered below, and four key questions are raised about treatment outcome and culture that need attention in future research.

5.04.13.1 How Effective are Tested Treatments with Ethnic Minority Children?

In general, children in the 19 studies improved significantly more than children in control conditions. Treatment showed a significant beneficial effect on externalizing problems in 79% of the group comparisons, and for internalizing problems the figure was 86%. On other outcomes, such as self-esteem, social skills, and family functioning, 46% of the comparisons showed significant treatment benefit. These figures appear somewhat more modest than the general trends seen in meta-analyses that apparently included predominantly Caucasian majority samples, but such a comparison is problematic because of numerous study-to-study differences in treated problems, types of treatment, and so forth. Direct comparison is far superior, but only one such comparison was identified in the 19 studies; Henggeler, Melton, and Smith (1992) found that African-American and Caucasian delinquents responded equally well to multisystemic treatment.

5.04.13.2 Is there Evidence of Treatment Type and Ethnic Group Interaction?

In a word, no. But this may be only because no complete test of such an interaction has been carried out. In the author's sample of 19 minority youth outcome studies, one study involved an initial step toward such a test. Szapocznik and colleagues (Szapocznik et al., 1989; Szapocznik, Kurtines, Santisteban, & Rio, 1990) tested the efficacy of structural family therapy (SFT) against individual psychodynamic child therapy (IPCT) with Hispanic families of boys with behavioral and emotional problems. Following treatment, SFT-treated children had fewer behavior problems than IPCT children, but neither group differed significantly from children in a recreational control condition. At follow up, family functioning improved substantially following SFT relative to IPCT; indeed, with IPCT, family functioning actually worsened over time. The findings seem consistent with Tharp's (1991) contention that family-based therapies are more appropriate than individual treatment for minority children. However, Szapocznik et al. did not include comparison groups of non-Hispanic youth treated with SFT and IPCT. Thus, it appears that the field still awaits a full test of treatment type and ethnicity interaction.

5.04.13.3 Outcomes of Therapist–Client Matching for Ethnicity or Language

Although nine of the 19 studies in the collection involved some attempt at ethnicity and/or language match, none provided a direct test of the impact of the match, for example, by comparing matched and unmatched therapist–child pairs. Hayes, Cunningham, and Robinson (1977) reported that counselor race (African-American vs. Caucasian) did not appear to influence treatment outcomes with test anxiety and poor school motivation among African-American children, but they did not present substantiating analyses. In general, those studies in which some form of matching was carried out did not seem to show notably better success rates than the remainder of the 19. Again, such global comparison across studies lacks the precision of the direct, within-study tests that are most needed to address the "matching" question.

5.04.13.4 Outcomes of Adapting Therapies Specifically for Ethnic Minority Children

Ten of the 19 studies involved some sort of adaptation of the treatment program to cultural characteristics of the minority sample. The adaptations ranged from narrowly focused changes such as depicting minority figures in modeling tasks to such extensive change as essentially designing entire programs for a particular ethnic minority group. The fact that only one of the "unadapted" studies focused on internalizing problems ruled out comparisons on that dimension; however, the percentage of comparisons showing significant positive treatment effects was somewhat higher for externalizing problems (83% vs. 75%) and for problems in the "other" category (57% vs. 33%).

Direct comparisons of adapted and unadapted methods within the same study are difficult to find. A study by Constantino, Malgady, and Rogler (1986) did find that maladjusted Puerto Rican children in a culturally adapted modeling program involving cuento or folklore therapy showed less aggressive behavior following treatment than those in an art/play therapy control condition (APT). However, since APT subjects were even more aggressive than those in the no-therapy (NT) condition, the findings may reflect the ineffectiveness of APT as much as the superiority of cuento therapy. A more robust test of any culture-specific treatment approach would entail comparison with another empirically supported approach (e.g., social skills training for aggression). Where culture-calibrated changes have been made to a standard treatment program, it will be important to carry out direct comparison of outcomes for minority children receiving the altered program vs. outcome for minority children receiving the standard program.

Generalizing across the various themes and questions reviewed above, the state of affairs regarding culture and child psychotherapy can be summarized succinctly: there are intriguing hypotheses and important questions that need attention, but the numerous direct comparisons needed to test the hypotheses and answer the questions are lacking. With concern about culture and mental health growing steadily, it seems likely that the next generation of research will include increased attention to these matters.

5.04.14 CONTEXT SENSITIVITY OF TREATMENTS

A sixth issue arises because the interventions involved in most treatment research are rather removed from the contexts in which children live their lives. Most researchers would agree that children do not develop as solitary beings in a sterile environment, but rather as active participants in complex, multifaceted physical and social systems. Yet most treatment outcome research with children involves interactions with a single therapist, or sometimes with a small group of unfamiliar children, in the sterile environment of the therapist's office or therapy room. Pretherapy assessment and treatment planning typically involve very limited sampling of the child's life circumstances and behavior at home, at school, or with familiar peers. This may limit the capacity of the therapist to fit interventions precisely to conditions and context of the individual child's problems. In the worst cases, the problem may tilt treatment development in the direction of "one-size-fits-all" or "cookie-cutter" therapies.

Numerous theorists and researchers (e.g., Bronfenbrenner, 1979, 1986; Masten, Best, & Garmezy, 1991) have emphasized the context boundedness of development, and discussed implications for adaptation and dysfunction. Others (e.g., Cicchetti & Toth, in press; Mash & Dozois, 1996) have noted the diverse ways in which the child's contexts and ecological systems can influence the development and expression of dysfunctional behavior and emotional states. Still others (e.g., Forehand, Lautenschlager, Faust, & Graziano, 1986; Kazdin, 1989) have noted that even what parents report (e.g., to assessors and therapists) regarding deviance and dysfunction in their children can be influenced by such diverse factors as parental psychopathology, marital discord, stress in the home, and even an intent to conceal harmful parental practices (e.g., abuse or neglect). Finally, it seems self-evident that the impact of psychotherapy with children may vary depending on the extent to which significant others in the child's contexts (e.g., parents, teachers) are involved and supportive of the process. The power of all the influences noted in this paragraph may be felt disproportionately in childhood, in part because children have such limited ability to select the contexts in which their development unfolds.

The message for treatment planners and treatment outcome researchers is that contextual factors and key individuals in the child's social environment (e.g., parents, teachers, siblings, peers) may need to figure significantly in pretreatment assessment, in treatment planning, in treatment delivery, and in outcome assessment. In general, these steps have only been taken in very limited and tentative ways in child psychotherapy research to date. There are some exceptions to this generalization, however, and noting a few of these may help illustrate what is possible in future child psychotherapy research.

In one approach, Lewinsohn and colleagues (see Lewinsohn, Clarke, Hops, & Andrews, 1990; Lewinsohn, Rohde, Clarke, Hops, & Seeley, 1994; Rohde, Lewinsohn, & Seeley, 1994) have created a parent counterpart to their Adolescent Coping with Depression group intervention. The objective is to promote parental understanding and acceptance of what is being taught to the adolescents, and to reduce family conflict by teaching parents some of the same communication and problem-solving skills their adolescents are learning. In another approach, such investigators as Szapocznik and colleagues (e.g., Szapocznik et al., 1989) treat problem behavior in Hispanic boys by means of structural family therapy. Webster-Stratton and colleagues (e.g., Webster-Stratton, Kolpacoff, & Hollinsworth, 1988) have developed a self-administered videotape therapy for families with conduct-problem children. Henggeler and colleagues (e.g., Henggeler, Melton, & Smith, 1992; Borduin et al., 1995), in perhaps the most context-sensitive approach yet developed, send therapists into the settings where juvenile offenders live their lives, working with them to develop treatments tailored to the strengths and limitations of their family, school, peer group, and neighborhood. Each of the intervention approaches cited here has shown positive effects relative to control groups, although Lewinsohn and colleagues have not yet found that adding parent training alone to their adolescent intervention improves benefits over and above treatment of adolescents only. Perhaps procedures that delve more deeply into the child's social systems are required to produce benefits greater than those of individually administered interventions.

Moving in the directions illustrated by these research teams certainly will complicate the work of treatment development and outcome assessment. On the other hand, such efforts seem essential if we are to assess the benefits of context-sensitive treatment. We need to find out what can be gained if we push beyond a narrow focus on child characteristics and toward a broader focus on potentiating and inhibiting forces in the social systems within which the child is growing up.

ACKNOWLEDGMENTS

The research program described in this chapter was supported through a Research Scientist Award (K05 MH01161) and research grants (R01 MH34210, R01 MH38450, R01 MH38240) from the National Institute of Mental Health, which I gratefully acknowledge. I also appreciate the important contributions made to this work by faculty and graduate student colleagues, clinic administrators and therapists, and the many children and parents who have participated in the research before, during, and after treatment.

5.05.1 THEORETICAL UNDERPINNINGS

Applied behavior analysis (ABA) has it roots in the various learning theories of psychology. The theories of Pavlov, Watson, Thorndike, and Hull (Bry, 1975) provided the early impetus for the development of modern day ABA. Despite the substantial contributions of these scholars, the pre-eminent theorist in the field has clearly been Burrhus Frederick Skinner. The theoretical work by Skinner (1938, 1953, 1957, 1969) on operant conditioning has been the foundation on which ABA has been established. Skinner developed his early theoretical formulations of operant conditioning from research in laboratories with rats and pigeons. His later writings moved more toward applications of the theory with humans. One of his most read works, *Walden Two* (Skinner, 1948), was a novel about the ways in which operant conditioning could be used to create a human utopia.

Although operant conditioning is the foundation of ABA procedures, it is important to indicate that this does not mean that ABA clinicians are of the view that all problem behavior of human beings is the product of operant conditioning. On the contrary, ABA clinicians see all human behavior as resulting from the complex interaction of a number of variables. A useful conceptualization of the determinants of behavior has been offered by Ross (1976), who argued that the variables that effect an individual's behavior are (i) long-term genetic/constitutional factors, (ii) past learning history, (iii) current physiological state, and (iv) current environmental factors. The first three of these, often referred to as organismic variables (Ollendick & Cerny, 1981), are seen as being important but not easily manipulated to effect behavior change. In contrast, environmental factors that effect behavior are more amenable to change. It is the manipulation of these environmental variables, primarily in accordance with the principles of operant conditioning, that is the basis of ABA interventions in clinical psychology.

The fundamental elements in the theory of operant conditioning are the behaviors that people engage in and the antecedents and consequences of those behaviors. In regard to the relationship between behaviors and their consequences, the future occurrence of behaviors is dependent upon the current consequences of those behaviors. Behaviors that are followed by reinforcement will increase in frequency. Reinforcement can occur in two conceptually different ways. First, it can involve the contingent presentation of a "pleasant" stimulus, called a positive reinforcer, with the process being termed positive reinforcement. Alternatively it can involve the contingent removal of an "unpleasant" stimulus, called a negative reinforcer, with this process termed negative reinforcement. It is important to note that the property of a stimulus being a positive reinforcer is defined purely in terms of the effect of that stimulus when it is presented contingent upon the occurrence of the behavior. If contingent presentation leads to an increase in the frequency of the behavior, the stimulus is a positive reinforcer. In a similar fashion, a negative reinforcer is defined in terms of its capacity to increase behavior when it is removed contingent upon the occurrence of the behavior.

Behaviors that are followed by punishment will decrease in frequency. In a similar manner to reinforcement, punishment can occur in two ways: by the contingent presentation of a negative reinforcer (in these circumstances the term "punisher" may be used), or the contingent removal of a positive reinforcer. It might be expected that these processes would be called positive and negative punishment. This has not been the practice. Some authors refer to them as type 1 and type 2 punishment. Others use the term "punishment" only for the presentation of a negative reinforcer (punisher), and use the term response cost for the contingent removal of a positive reinforcer.

Finally, behaviors that are followed neither by reinforcement nor punishment will decrease in frequency, with this phenomenon being known as extinction.

A substantial amount of early operant conditioning research examined ways in which variations in the delivery of reinforcement effected the behavior it was contingent upon. For example, it was found that reinforcement delivered immediately after the occurrence of the behavior is more effective in increasing the rate of the behavior than reinforcement which is delayed for a short period of time. Of particular interest in regard to variation in delivery of reinforcement was the effect of not providing reinforcement for every occurrence of the behavior. Providing reinforcement for every occurrence became known as using a continuous schedule of reinforcement, whereas some variation of this is referred to as an intermittent schedule of reinforcement. The effects of various intermittent schedules on the rate of increase of behavior and subsequent extinction of the behavior were studied. Initial variations were made in the ratio of reinforcement (the number of responses that had to be emitted before reinforcement was provided), and the interval of reinforcement (the period of time that would be allowed to elapse before reinforcement was provided for the next response emitted). Ratio schedules could be fixed, in that reinforcement was provided after a set number of responses, or could be variable, in that reinforcement was provided after a varying number of responses. Similarly, interval schedules could involve a fixed or variable period of time. The effects of all types of schedules have been well documented in the literature, but one important finding for the ABA field is that to teach new behaviors it is better to begin with a continuous schedule. When the behavior is established, however, it is advisable to move to variable schedules as they are more resistant to extinction once learning has taken place.

As has been described, the effects of consequences on the future occurrence of behavior is a central component of the theory of operant conditioning. In addition, however, events or stimuli that precede the occurrence of the behavior are also important. These are usually referred to as the antecedents of the behavior. Antecedents go with the behavior and its consequences to make up the antecedent–behavior–consequence sequence that is so important in the use of ABA in applied settings.

One way in which antecedent stimuli are important in operant conditioning is that they can act as a signal that a behavior will be reinforced if the behavior is emitted. A young child might find that if he asks his mother for some candy, the answer will be no. If, however, he asks his father, the answer is yes. The child quickly learns to ask the father and not the mother. In these circumstances, discrimination learning has taken place, and the father is the discriminative stimulus for the behavior of asking for candy. The systematic reinforcement of a behavior under some stimulus conditions but not others is used to promote discrimination, and is referred to a discrimination training. Such training is an important component of many interventions based on ABA.

Traditionally, operant conditioning theory focused only on those antecedents and consequences that were temporally contiguous with the behavior. These are referred to as proximal antecedents and consequences. It became clear, however, that antecedents and consequences that are temporally removed from the behavior can also be important. These are referred to as distal antecedents and consequences.

In regard to distal consequences, they may exert more influence on a particular behavior than those that are more immediate. A student, for example, may engage in long hours of study during the weekend, resulting in fatigue and the missing of social activities (immediate punishers), for the sake of completing an assignment due on Monday morning (a powerful reinforcer).

Distal antecedents that are gaining increased attention in the use of ABA are referred to as setting events (Wahler & Fox, 1981). These are events that alter the probability that a proximal antecedent will be discriminative for the occurrence of a particular behavior. By way of example, a child at school may usually respond to a request from the teacher in a cheerful and compliant manner. However, on the days following domestic disruptions at home, the child is moody and non-compliant. Here the domestic disruptions act as a setting event that alters the probability of the child responding positively to the teacher.

An important point in relation to the antecedent–behavior–consequence sequence is that a single behavior may be associated with more than one antecedent and/or more than one consequence. For example, the behavior of one child hitting another child could be occasioned by the other child calling her a name, the other child having a toy that is wanted, or in response to a dare from a third child. Similarly, the aggressive behavior could have many consequences, for example the other child cries, the aggressive child gains the coveted toy, and also receives attention from an adult, all of which could be reinforcing.

One area of operant theory that is often not given much prominence in basic texts on ABA is that of rule-governed behavior. To illustrate this concept, let us take the example of a child who is usually slow with his work at school. One day the frustrated teacher tells him that if he completes all his mathematics problems in class, he will be permitted to go to play early. The child completes the problems and goes to play early. The behavior of completing the problems was not established by contingent reinforcement, but is an example of rule-governed behavior. Skinner defined a rule as a verbal statement that specifies the conditions under which a behavior is to occur, the behavior itself, and the consequence that will follow the behavior. The child in our example followed the rule "If you complete all problems in class, you will get to go to play early." However, such rule-governed behavior will occur only if certain conditions are met. First, the child must possess sufficient language skill to understand the rule. Second, the general response class of following similar rules must have been established. In this case, the child's learning history must be such that he has been contingently reinforced for following such rules in the past.

Skinner distinguished between two types of rules, one he called a command and the other advice. The word "command" is used when the person stating the rule controls the availability of the reinforcer. The situation given above is an example of a command rule. The teacher controlled the availability of early access to play. The word "advice" is used for those situations in which the person stating the rule does not control the availability of the reinforcer, but is aware of the contingency. An example of such a rule would be a parent telling her child "If you poke that stick into the electricity outlet, you will get a shock." A knowledge of the method of establishing or changing rule-governed behavior is progressively becoming more important in clinical applications of ABA.

It is critical that practitioners using ABA procedures in applied settings be thoroughly familiar with the fundamental theoretical concepts. A sound understanding of them is not only necessary for the development of effective treatment programs, it is impossible to effectively "trouble shoot" intervention programs if the clinician does not have mastery of the theory underlying the design of the program.

5.05.2 HISTORY OF THE APPROACH

As indicated in Section 5.05.1, ABA has derived primarily from the principles of learning, particularly operant conditioning. The refinement of these principles was effected through experimental research with animals, and was published through eminent journals such as the *Journal of the Experimental Analysis of Behavior*.

The application of ABA procedures with humans did not begin in any substantial way until the 1950s, when learning-theory-based approaches to intervention in human problems became a serious competitor to the traditional psychodynamic approaches derived from Freud and other psychoanalysts. Proponents of learning-theory-based approaches were dissatisfied with three major aspects of traditional approaches. The first was the heavy reliance on the use of putative intrapsychic constructs to explain behavior. Learning theorists preferred to study the behavior directly. The second was a propensity to explain abnormal behavior in terms of a medical or illness model. Learning theorists saw abnormality as being at the end of the continuum of normal development, and hence as being quantitatively, not qualitatively, different from normal behavior. The final point of dissatisfaction was with what was seen as unsubstantiated claims for success of traditional psychodynamic approaches. Hence, learning theorists placed great emphasis on experimental demonstrations of treatment efficacy.

Despite these common concerns with traditional therapies, learning-theory-based therapy did not emerge as a single entity. In the early days, two relatively different approaches were developed. ABA was one of these, and as indicated earlier, grew out of the operant conditioning work of Skinner. The other approach was founded more on classical conditioning, particularly the work of Pavlov (1927) and Hull (1943). Development of this approach for work with humans can probably be attributed to Eysenck (1959) and Wolpe (1958). A major difference between the two approaches was the importance placed on private or covert events within humans, such as thinking and feeling. Although Skinner recognized the existence of private events, he considered that there were serious limitations in being able to study them scientifically, and hence ABA clinicians initially focused on overt, observable behavior. In contrast, proponents of the other approach were quite comfortable working with constructs such as anxiety and fear. They considered that these processes were governed by the same principles of learning as were overt behaviors (Agras, Kazdin, & Wilson, 1979).

As time passed, further approaches developed within the framework of learning theory approaches to therapy. The 1960s and 1970s saw the evolution of what became known as cognitive behavior therapies. Perhaps the first of these was social learning theory. The principal theoretician in the development of social learning theory was Bandura (1969, 1977), who argued that cognitive processes played a mediational role between the antecedent and consequent stimuli that impinged on humans. Bandura's experimental work on observational learning has been particularly useful in explaining the acquisition of many human behaviors, but also is an important theoretical component of therapeutic modeling. Bandura's construct of self-efficacy has also proven to be popular in clinical practice. He argued that the knowledge by a person that a particular behavior would be reinforced was not necessarily enough to motivate the person to perform that behavior. What also was necessary was the person's belief that he or she had the ability to perform that behavior.

Other theoreticians who have contributed to the field of cognitive behavior therapy are Ellis (1979), Mahoney (1974), and Meichenbaum (1977). While the final products that they have developed are all a little different from each other, a key element that runs through all of them is what is referred to a cognitive restructuring. This process essentially involves teaching individuals to change their behavior by changing the ways in which they think about their behavior and its consequences.

While all of these developments within the framework of learning theory approaches to therapy have been important, the focus in this chapter is on ABA, although much of what is described as being the application of ABA incorporates elements from the other approaches.

Before moving on to the assessment and clinical formulation of the ABA approach, some comments about its applications could be informative. Because ABA first emerged as the application of principles derived from laboratory research to the resolution of human problems (Baer, Wolf, & Risley, 1968), many early applications of ABA were with psychiatrically and developmentally disabled people. The research by Ayllon and Michael (1959) on teaching psychiatric nurses to be behavioral engineers has been seen as the first publication in the emergence of ABA. The first issue of the *Journal of Applied Behavior Analysis* (*JABA*) in 1968 is probably a better-recognized marker of the beginning of the widespread usage of the approach. Many of the early *JABA* articles were in the disability field. As time has progressed, the principles of ABA have begun to be used in wide variety of fields. Engelmann and Carnine (1982) used ABA as a major plank in the development of their theory of instruction that is now the basis of many educational programs (Kameenui & Simmonds, 1990). Sulzer-Azaroff (1982) has used ABA in the promotion of better practices in the field of occupational health and safety, and there are many examples of the use of ABA in the organizational behavior and management literature (e.g., Brethower, 1972; Connellan, 1978). Finally, Biglan, Metzler, and Ary (1994) report on the use of ABA procedures to change behavior on a community-wide basis. In the remainder of this chapter, the focus will be on the use of ABA in the treatment of clinical problems of children and adolescents.

5.05.3 ASSESSMENT AND CLINICAL FORMULATION

There are several excellent texts available that give a full description of assessment and intervention procedures in ABA. To mention just a few authors, there is Cooper, Heron, and Heward (1987), Grant and Evans (1994), Martin and Pear (1996), and Sulzer-Azaroff and Mayer (1991). This chapter summarizes procedures that are more fully covered in these texts.

There are three steps involved in assessment and clinical formulation using the procedures of ABA: specification of the behavior, measurement of the behavior, and assessment of the function of the behavior.

5.05.3.1 Specification of Behavior

The first step in assessment and clinical formulation is the specification or description of the behavior of interest. It is essential that this specification be as precise as possible so that any confusion about what is meant is minimized. Terms such as "aggressive" or "self-injurious" are useful only as general descriptors of classes of behavior. They are not used in an ABA assessment as they can be interpreted in many different ways by observers. What is necessary is an accurate description of the behavior of interest; for example, the child "punches other children," or "slaps himself in the face." It is only when a precise description of the behavior is formulated that measurement, the second step in the formulation, can be reliably carried out.

5.05.3.2 Measurement of Behavior

Several methods of measuring behavior have been developed, the most commonly used being frequency counts, duration measures, counting of permanent products, and time sampling procedures, although other measures such as intensity and latency can be useful.

A frequency count involves, as the name suggests, counting the number of times the behavior occurs in a given time period, for example, during the course of one day. A duration measure involves measuring the total time the child spends engaged in the behavior of interest, again usually during the course of a day. The choice of measurement method is based on a consideration of which method will "give the best picture" of what is actually happening. To illustrate this, consider a child who punches other children. Each punch is quite discrete, and a frequency count will give an accurate assessment of the extent of the problem. In contrast, consider the child who sucks his thumb so much that physical damage is occurring. If this child puts his thumb in his mouth after breakfast and only takes it out to have lunch, a frequency count would record only one instance for that morning, not really reflecting the extent of the problem. A duration measure would clearly be better in this case.

Many behaviors result in relatively permanent products that can be counted, with the resulting sum being the measure of the occurrence of the behavior. The mathematics output of a child at school can be measured by the number of problems completed. A person who is trying to give up smoking could measure the amount of smoking by counting cigarette butts in an ashtray at the end of the day.

Time sampling is more complex than the frequency, duration, and permanent product methods, and involves breaking the observation period into relatively short time intervals (e.g., 15 seconds), and then noting whether or not the behavior occurs during that interval. There are variations of time sampling referred to as total interval, partial interval, and momentary time sampling. The term "total interval" is used when the behavior of interest has to occur for the complete duration of the time interval for it to be scored as an occurrence. "Partial interval" is used when the behavior only has to occur at some time during the interval, and not for the total interval. The term "momentary" is used when a behavior is scored only if it occurs at a particular instant in the interval, usually the end of the interval. While time sampling procedures are more labor-intensive than frequency or duration methods, they have some advantages in that several behaviors of several children can be observed simultaneously. The particular type of time sampling procedure used will depend on matters such as the type of behaviors being assessed and the time available to the observer.

Sometimes clinicians will be interested not only in how often or for how long a behavior occurs but also how strong or intense it is, and hence would introduce an intensity measure. A clinician treating a child who inappropriately calls out in public places might be interested in the volume of the calling out. Volume would be important if the objective of intervention was not to eliminate public conversation, but to reduce it to a socially acceptable level.

A final measure that might be used in assessing a behavior is that of latency, or the time that elapses between some important event and the onset of the behavior by the child. Latency measures are often used when the behavior of interest is compliance by the child with some instruction given by a parent or other caregiver.

There are two reasons why clinicians need to take precise measurements of the behaviors of interest as part of the assessment process. The first is related to making a decision about whether subsequent intervention is actually warranted. For example, take the case of a child who is referred by her parents because of a "low" level of compliance to instructions given by them. An initial assessment of the child's rate of compliance might indicate that her compliance is typical for a child of her developmental level. Under these circumstances, intervention to improve the child's compliance would not be indicated. Instead, the parents need assistance with improving their knowledge of child development, and perhaps some help with accepting the child as she is.

In most cases of the application of ABA, the initial measurement of the behavior of interest does indicate that some intervention is warranted. On some occasions, the measurement will show that the behavior is occurring more often than considered appropriate. This is referred to as having a behavioral excess, and hence the objective of intervention will be to reduce the occurrence of the behavior (weaken it), perhaps even to totally eliminate it. On other occasions, the measurement will show that behavior is not occurring as often as considered appropriate. This is referred to as having a behavioral deficit, and the objective of intervention will be to increase its occurrence (strengthen it). Once a behavior has been identified as being in need of either strengthening or weakening, it is referred to as a target behavior.

The second reason for taking precise measurements of the behaviors of interest is related to the need to evaluate the efficacy of any intervention that is proceeded with. Under these circumstances, the initial measurements form the baseline against which intervention efforts are evaluated. This means, of course, that measurement of the behaviors must continue during intervention. The issue of determining the efficacy of ABA intervention is dealt with more fully in Section 5.05.5.1.

5.05.3.3 Assessment of the Function of Behavior

The third step in clinical formulation is the assessment of the function of the target behavior, that is, to identify the antecedents and consequences which are functionally related to the behavior. Before a fuller discussion of this element is possible, a distinction needs to be made between the topography of a behavior and the function of a behavior. The topography of a behavior is what the person does, and can be readily seen by an observer. The function of the behavior is the purpose of the behavior, and this is much less obvious to the observer.

The distinction between topography and function is a very important one in ABA because the relationship between a behavior and its antecedents and consequences is to do with the function of the behavior, not the topography. To illustrate this, two scenarios can be considered.

The first considers two developmentally-delayed children who frequently slap their faces to the extent that physical damage is caused. One may do it, having learned that it is an effective way of getting attention from other people, that is, the behavior is being maintained by positive reinforcement. The second child may do it having learned that people who are making demands, stop it and go away, that is, the behavior is being maintained by negative reinforcement. The behaviors of both children may have exactly the same topography, but they have quite different functions. Hence, despite the similarity of the topography of the behaviors, the intervention programs will need to be very different and be based on the analysis of function of the behaviors.

In the second scenario, again consider two developmentally delayed children. Like the first child in the other scenario, one slaps his face because he has learned that it gains adult attention. The second child frequently takes his clothes off because he has found that this gains attention from other people. In both cases, the behaviors which are quite different topographically are performing the same function. Here, the intervention programs are likely to be quite similar.

A quite common mistake made by clinicians not skilled in ABA is that they design intervention programs around behavior topographies. Such an approach may achieve an occasional success, but in general it will produce failure.

In order to adequately identify the antecedents and consequences that are functionally related to the target behavior, information about the child and behavior must be gathered from an extensive range of sources. The most commonly used methods of information collection include the use of interviews, completion of written materials, and direct observation of the target behavior and its antecedents and consequences.

5.05.3.3.1 Interviews

When working with young children or children with developmental delay, the person initially interviewed is the child's caregiver, usually the parent. Protocols for the conduct of such interviews have been published (Table 1; Murphy et al., 1985; Webster-Stratton & Herbert, 1994). One focus of the interview is to gather as much information about the target behavior as possible. This will include the precise specification of the behavior, estimates of the occurrence of the behavior, and suggestions about potential antecedents and consequences that are functionally related to it. In addition, however, other information needs to be gleaned from parents about the skill levels of the child and the child's preferences (potential reinforcers). These could be important in the design of an intervention program. Another issue to be discussed is what treatments have been tried in the past, presumably ineffectively. Such information is critical to the detail of what is included in an intervention program. It is usual that all of these matters are discussed at an initial interview with caregivers, the final part of which typically involves the establishment of procedures to collect baseline data.

When working with older children and adolescents, an interview might be conducted with them. Additionally, interviews might be conducted with significant others in the child's life, for example, teachers. Many of the same issues are covered in these interviews as those with caregivers. These interviews do, of course, allow the clinician to hear a different, and probably useful, perspective on the issues.

5.05.3.3.2 Written materials

In addition to the use of interviews, information can be gathered using a range of written materials. These would typically include standardized checklists about the child, for example, the Child Behavior Checklist (Achenbach & Edelbrock, 1983). If relevant, they may also include checklists about the functioning of other members, for example, measures of parental relationships or affective status.

Such written material can be of value for several reasons. First, it often includes normative data and can provide information on the occurrence of the behavior of interest relative to the general population. This information should be relevant in deciding whether or not to try to change the behavior of interest. Second, the use of standardized checklists might bring the clinician's attention to some relevant matters that have not been mentioned in any interviews conducted. Finally, if an intervention is carried out, the checklist can also be administered after intervention, and hence add to other information collected to evaluate the efficacy of the intervention.

5.05.3.3.3 Direct observation of the behavior

The final general source of information is that provided by direct observation of the behavior. Mostly, this is done by caregivers who collect data on the target behavior using frequency counts or duration measures. Obtaining good-quality data from caregivers is not always an easy task. It is important for clinicians to realize that for this part of the exercise it is the caregiver's recording behavior that is important, and attention must be paid to the antecedents and consequences of that behavior. First, the clinician needs to provide structured data collection sheets, clear instructions, and

Table 1 An interview schedule for use in the behavioral assessment of children's problems.

The "client" referred to below is a significant person in the referred child's life, for example, a parent

1. The establishment

(i) Introduce yourself to the client (name and profession; how you like to be addressed; introduce any observer or colleague—name and role)
(ii) Engage in "small talk" to put the client at ease
(iii) Direct client to an appropriate chair if the interview is in an office (have chairs and furniture prearranged to facilitate communication, etc.)

Remember that this period is critical to the development of a good client–therapist relationship. Such a relationship is essential for therapeutic success

2. General

(i) State purpose(s) of interview
The client should be given a general statement on the purpose of the interview. This is important because some clients expect an immediate answer to their problem. Over the course of the interview it may be necessary to remind the client that management advice is not possible at this stage

(ii) Seek permission for note taking, etc.
Permission should be obtained from the client for note taking. Usually this is not a problem in terms of client permission. Should audio- or video-recording be thought to be an advantage, seek additional prior permission

(iii) Seek client's perception of problem
At this stage it is helpful to ask the client about the nature of the problem. This is simply to prompt clients to give their perception of why they have come to see you. The description given may not be satisfactory to you or the client at this stage, but continued exploration about the nature of the problem will follow later on in the interview. The idea of asking the question here is partially to set the stage for the next step, gathering general background information. Terminate this step by saying that you will come back to talking about the problem later, but first you want to obtain some other information about the child

(iv) Determine referral agency
Obtain or check details of the referring agency (professional's name, agency, phone number, etc.). Remember that good liaison with other agencies in the community is essential, but also that dual management can be wasteful, confusing, or deleterious

3. General background information

(i) Biographical information of child

(a) name,
(b) age (including date of birth),
(c) address, and
(d) telephone number

(ii) Family background

Here the interviewer collects information about:
(a) whether the mother and father (or others filling these roles) are present in the household,
(b) what employment, if any, parents (or other caretakers) have,
(c) number and ages of siblings in the family,
(d) any unusual family organizational pattern, such as an aunty or cousin living with the family, and
(e) quality of relationship between the target child and other family or household members

(iii) Educational background

Here careful detail of the child's educational background is recorded, including:
(a) number and type of schools attended,
(b) general progress at school including any grades repeated,
(c) any history of conflict with teachers,
(d) current teacher's name, and
(e) relationships with peers

(iv) Medical background

Here the interviewer lists any information regarding the child's medical background, particularly anything that is slightly out of the ordinary. Remember to question regarding:
(a) general development milestones and behavior patterns,
(b) childhood illnesses, and
(c) any medication the child is currently on

Table 1 (continued)

If the behavioral interviewer is unsure about "normal" developmental rates of infants and children, standardized developmental checklists should be used

The above areas need to be explored because (a) most clients receiving clinical service expect such areas to be addressed, and (b) the information helps the clinician to appreciate the context of the problem, assists the clinician's choice of target behaviors, guides selection of assessment devices to be used, and identifies possible barriers to particular treatment programs

4. Specific information build-up

(i) Investigate the precise nature of the problem
Here the interviewer seeks to have the client state precisely what the nature of the problem is. Some clients may need extra time to articulate the problem, and some may need prompting to be specific

(ii) Investigate the extent of the problem
Here the interviewer seeks to obtain some estimate from the client about the frequency or the duration of the previously described behavior(s). At this point, self-report information is relied upon; at a later stage, more objective methods of assessment will need to be introduced

(iii) Investigate the apparent antecedents and consequences of the problem
Here the interviewer seeks to draw from the client a rough idea of what he or she perceives to be the antecedents and consequences associated with the particular behavior(s)
Choice of language on the part of the clinician is very important. Phrases like "what happens before," "events that trigger" (antecedents), and "what happens during and after" (consequences) are better for most clients

(iv) Determine what has previously been tried
Clients should be assisted to state previous attempts to handle the problem, and advice received from other agencies previously or currently involved

5. Clarification of expectations

(i) Establish agreement on the goal of treatment
Here the interviewer needs to come to agreement with the client regarding the goal of treatment. The goal must be stated in specific terms

(ii) Determine suitability of agency
State whether or not this agency is suitable for helping to achieve that goal, and if not, give client referral options

(iii) Establish realistic timeline for improvement
Ensure that the client is aware that the therapist does not have a magic wand to wave over the problem child and be able to immediately convert him or her from being a problem to no problem at all

(iv) Involvement of client
Impress upon the client the need for him or her to be actively involved in the intervention program, and if they decide to proceed that this will necessarily require active participation by the client

6. Setting of homework (if feasible at this stage)

The interviewer here needs to set very precise homework for the client to carry out during the subsequent period of time. Usually 1 week elapses between the first and second interviews. The specific instructions would usually require the collection of baseline data and the identification of the antecedents and consequences associated with the target behavior. Appropriate antecedent stimulus control of the client's behavior is usually best achieved through the handing out of very structured sheets that client has to fill in during the week and return at the next interview. It is important at the conclusion of the interview to make sure that the client is able to repeat precisely what is expected of him or her by the interviewer. (In many cases this homework setting can take up to 1 hour, so a separate interview for this purpose may be necessary)

7. Scheduling of next appointment

8. Termination of interview

Again remember the importance of a good client–therapist relationship

perhaps some role play practice at filling in the sheets. Although baseline data are usually collected for a period of two weeks, many clinicians find that a check-up phone call 2 days into data collection is important. Such a call will help overcome any difficulties encountered in the first days and increase the probability that the caregiver will return with useful data. These are all examples of establishing antecedent stimulus control over the data-collecting behavior of the caregivers. As ongoing data collection is important for evaluating interventions, the behavior of the caregivers needs to be reinforced by the clinician.

Older children and adolescents might also participate in collecting direct observation data on their own behavior. This would be absolutely necessary if the target behavior was covert; for example, having obsessive thoughts.

The final way in which direct observation data can be collected is by the use of independent observers who enter into the natural environment of the child. A potential difficulty to be addressed here is the extent to which the presence of an outsider is reactive and has an influence on the behavior being observed. The use of independent observers in standard clinical practice is often a luxury which cannot be afforded, and hence their use is often restricted to research settings.

5.05.3.3.4 Developing a hypothesis regarding the function of the behavior

When a broad set of information has been collected by the various methods described above, the clinician is in a position to formulate hypotheses about the functions of target behaviors. This task is a little like putting together a jigsaw puzzle. Some relevant information will be gathered from interviews, some more will result from written material, and even more from direct observations. Not always will the information from different sources be consistent. When the clinician stands back, as it were, a picture will emerge that suggests a potential functional relationship between the target behavior and its antecedents and consequences.

The extent to which this hypothesized relationship is correct can only be tested by manipulation of those antecedents and consequences via a carefully designed intervention program, and the ongoing measurement of the target behavior. If the behavior changes in the desired direction, the hypothesis has been supported (perhaps not proven, but this matter will be discussed further in Section 5.05.5.1). If the program has been implemented as intended and the behavior does not change in the desired direction, the hypothesis is not supported, and the clinician needs to go back to the drawing board. The introduction of the intervention tests the hypothesis. This hypothesis-testing process is a defining feature of the ABA approach to clinical intervention.

5.05.4 DESCRIPTION OF INTERVENTION PROCEDURES AND PROPOSED MECHANISMS OF CHANGE

As has been described earlier, the logical outcome of the completion of an ABA assessment is the development of an intervention program that is designed to strengthen or weaken the target behavior. Such a program will involve the use of procedures developed from the basic principles of operant conditioning described earlier. It is important to point out that a comprehensive intervention program for a given child may involve more than one target behavior, and hence involve the simultaneous application of more than one procedure. For purposes of clarity, however, each procedure will be described separately here. First, there will be coverage of the relatively specific procedures used to strengthen behavior. Then there will be a discussion of the procedures for weakening behavior. Finally, there will be a discussion of complex procedures for strengthening and weakening behaviors.

5.05.4.1 Procedures for Strengthening Behavior

The most commonly used procedures for strengthening behavior are the systematic use of reinforcement, prompting, shaping, chaining, and modeling.

5.05.4.1.1 Systematic use of reinforcement

The most straightforward procedure for strengthening behavior is simply to wait for the behavior to occur, and then to reinforce it. However, there are some important issues related to this seemingly straightforward process. Perhaps the most important of these is to select an appropriate reinforcer. It must be remembered that a reinforcer is defined in terms of its effect on the behavior it is contingent upon. Clinicians can err in what they think will be reinforcing for particular children. The information collected in the assessment phase is critical for the right choice of an effective reinforcer, and this is not always an easy task. Some clinicians develop what are termed reinforcement menus, or lists of things that are potentially reinforcing, and then have the child or caregiver select from the menu. Another very helpful hint is to use what is known as the Premack principle. Premack (1959) noted that the activities children chose to engage in during their free time could be used to reinforce other, less-preferred activities. He technically defined this as using higher-probability behaviors to reinforce lower-probability behaviors. The importance of the principle is that if you are having trouble identifying what is reinforcing for children, observe what they do in their free time.

Reinforcers vary in nature and can be classified in a number of ways. One of the earliest distinctions made was between primary and secondary reinforcers. A primary reinforcer, sometimes referred to as an unconditioned reinforcer, is one that does not depend on learning to have taken place for it to develop its reinforcing properties. Food, water, and warmth are examples of such primary reinforcers. In contrast, learning has been involved in secondary or conditioned reinforcers developing their reinforcing properties. For example, some children find playing games on a computer to be very reinforcing. For this to have happened, some learning about the computer and the particular game must have taken place. It can be argued that there is limited clinical usefulness in the distinction between primary and secondary reinforcers as ethical considerations dictate that children have a fundamental right to unrestricted access to most primary reinforcers, and hence they should not be used in ABA programs. It is the case, however, that edible reinforcers such as candy have been used successfully to motivate children who do not respond to secondary reinforcers.

A second distinction that is made in regard to types of reinforcers is that between naturally occurring and artificial reinforcers. A naturally occurring reinforcer is one that is readily available and typically used in the setting in which the ABA program is being conducted. In most homes, reinforcers such as parent attention, pocket money, and access to television are available to children. Unfortunately, these reinforcers are often given to the children in an unsystematic or unplanned manner. An artificial reinforcer is one that is not usually available in the setting, but is brought in for the purposes of the program. Candy is not usually used as a reinforcer in most classrooms but could be introduced for use in a program for a special purpose. It is generally advisable for clinicians to use artificial reinforcers only when absolutely necessary, as the fading of such reinforcers can be more difficult than is the case for naturally occurring reinforcers.

A third distinction that is made is between extrinsic and intrinsic reinforcers. An extrinsic reinforcer is one that is quite separate from the behavior that it is reinforcing in that the behavior could occur and not be followed by the reinforcer. If a clinician is using praise to reinforce a child's behavior, the behavior can be allowed to occur without the reinforcement being administered. An intrinsic reinforcer can be viewed as one that is actually part of the behavior. The behavior is reinforcing by itself and does not need an extrinsic reinforcer to maintain it. Most children do not need to be extrinsically reinforced for watching their favorite show on television. They do it because they like it. The distinction between intrinsic and extrinsic reinforcement can be clinically important. Some behaviors, for example reading, may initially need to be extrinsically reinforced to get them going, but once established, can be maintained by their own intrinsic reinforcement.

Yet another way of distinguishing among reinforcers is to classify them based on the broad type of reinforcer. The types listed can vary among authors in the field, but a common list includes social, food, activity, and token reinforcers. Social reinforcers include praise, hugs, or attention from another person. As the name suggests, food reinforcers are things the child can eat. Rather than being basic food requirements, which, as mentioned earlier, are problematical from an ethical viewpoint, they are special treats that the child does not have regular access to. Activity reinforcers are those things that the child likes to do, for example, playing games and watching television. Finally, token reinforcers do not have value in themselves but derive their value from what they can be exchanged for. Many classroom teachers have children earning points for completion of academic work, and then allow the children to exchange those points for back-up reinforcers such as extra time at recess or reduced homework. Money is certainly the most frequently used token reinforcer.

A final point to be made in regard to the systematic use of reinforcement to strengthen a target behavior is that the fundamental principles derived from learning theory need to be adhered to. Reinforcement usually needs to be immediate, particularly with children at a low developmental level. If another behavior occurs between the target behavior and the delivery of the reinforcement, the more recent behavior might be the one that is strengthened. The second behavior under these circumstances is usually referred to as superstitious behavior. Also, attention needs to be paid to what is known about schedules of reinforcement. A continuous schedule needs to be used to maximize the rate of development of the new behavior, and then there should be a move to an intermittent schedule, referred to as a thinning of the reinforcement, to make the behavior more resistant to extinction.

5.05.4.1.2 Prompting

The use of systematic reinforcement to strengthen a behavior can only be effective if the behavior occurs in the first place. If it is not occurring, it needs to be prompted in some way, and it can then be reinforced. Prompts can take a variety of forms, but can be categorized as being physical, verbal, or visual prompts.

A physical prompt is one in which the child is given some physical assistance to perform the required response. Many parents use physical prompts to teach their children to learn feeding and dressing tasks. Care needs to be taken in determining the precise manner of using physical prompts. For example, when teaching a child to use a spoon, it is better to stand behind the child with the assisting hand over the child's hand. Such placement minimizes distraction for the child and allows for co-active movement of adult and child from the bowl to the mouth. As with all prompts, this prompt will need to be faded as the behavior becomes established over several trials, and this can be done by movement of the adult hand slowly up the arm of the child.

A verbal prompt is one that involves the use of spoken words or sounds to help the child perform the behavior. A boy learning to dress himself might be prompted to "hold your shorts in front of you, now put one leg in, etc.," or a child learning to read but stumbles on a word might be prompted to "say the sound of the first letter."

As the name suggests, a visual prompt is something the child sees that helps with the response. If a child is sorting blocks according to shape, the teacher might prompt by pointing to the correct container. This is often referred to as a gestural prompt. A picture placed on the refrigerator to remind a child to empty the trash would also be a visual prompt. Written notes can also be considered to be visual prompts, although some authors consider these to be verbal prompts.

All prompts need to be faded as the target behavior becomes stronger. The way in which this is done will vary depending upon the task in question, but in general the procedure is to start with a strong prompt and weaken it progressively, but not so fast that the target behavior is lost. It must be remembered that the purpose of prompting is to get the behavior to occur so that it can be reinforced, and reinforcement should not usually be thinned until the prompt is removed.

5.05.4.1.3 Shaping

Some behaviors are so complex that no amount of prompting will elicit the desired final form of it, resulting in no reinforcement, and hence no behavior change. Under these circumstances, a decision is made to reinforce only some approximation to the desired behavior. Progressively, closer approximations to the behavior are required before reinforcement is forthcoming, and eventually the final behavior will have been totally shaped.

5.05.4.1.4 Chaining

Many behaviors that are of interest to clinicians are complex behaviors consisting of a number of smaller behaviors linked together to form a behavior chain. Each link of the chain can be conceptualized within the usual antecedent–behavior–consequence sequence, and is taught using the procedures described thus far. Additionally, however, the completion of one link is viewed as the antecedent stimulus occasioning the performance of the next link, which in turn becomes the stimulus for the occurrence of the next. The process of developing the final chain can be of three types, forward chaining, backward chaining, and total task training.

When using forward chaining, the initial link of the chain is the first taught, then the second, then the third, and so on until the complete chain has been learned. Prompting, shaping, and reinforcing could all be used in the teaching of each separate link. While learning each link, the child is usually helped through all of the remaining links so that task completion can be reinforced. Teaching a child to put on a pair of trousers might be a typical skill taught by using forward chaining.

When using backward chaining (sometimes called reverse chaining) it is the final link in the chain that is taught first, then the others are proceeded with working in reverse order. The initial link thus becomes the last taught. This approach is considered desirable when the complex behavior leads to some naturally occurring reinforcer being available, for example a child learning to use a spoon might start with the final link of placing the food in his mouth. This contiguity of naturally occurring reinforcement and task completion is considered to provide better motivation to learn the earlier links in the chain.

Whereas forward and backward chaining are typically used when a child has mastered few if any of the separate behavioral links, total task training is more efficient for situations in which the child has mastered most or all of the links. A child who has mastered simple addition, subtraction, multiplication, and division would typically be taught the behavioral chain involved in completing a long division by using a total task method.

5.05.4.1.5 Modeling

Modeling is sometimes described as being an example of visual prompting, but modeling used properly as a therapeutic technique involves more than just a prompt. Modeling as a technique depends to a large extent on the fact that people can and do learn much from imitating others. Children often engage in incidental imitation of others, and, much to the chagrin of parents, they often pick up behaviors other than those preferred by parents. Imitation is important but is only one of the many components of therapeutic modeling. As Bandura (1969) has pointed out, modeling involves attentional, retentional, motor reproduction, and motivational components. In practical terms, the full modeling procedure includes the following steps:

(i) Explanation to the learner to pay attention to the relevant aspects of the behavior to be modeled (e.g., "Look at how the model does . . .").

(ii) Recall by the learner of the aspects of the behaviors to be observed.

(iii) Reinforcement of this recall and corrective feedback by the clinician as necessary.

(iv) The demonstration of the desired behavior by the clinician.

(v) Recall by the learner of what was observed.

(vi) Reinforcement of this recall and corrective feedback by the clinician as necessary.

(vii) Performance of the behavior by the learner.

(viii) Reinforcement of this performance and corrective feedback by the clinician as necessary.

(ix) Repeat of the above steps as necessary.

This procedure will vary depending on the particular case. The model can be live or on film.

5.05.4.2 Procedures for Weakening Behavior

The most commonly used procedures for weakening behavior are differential reinforcement of incompatible behavior (DRI), differential reinforcement of alternate behavior (DRA), differential reinforcement of other behavior (DRO), extinction, timeout, overcorrection, and punishment. As can be seen in Sections 5.05.4.2.1–5.05.4.2.3, several of these procedures for weakening behavior involve a concurrent strengthening of a nontarget behavior.

5.05.4.2.1 Differential reinforcement of incompatible behavior

Differential reinforcement of incompatible behavior (DRI) is a weakening procedure that is based on reinforcement. The behavior that is reinforced is not the target behavior, as this would clearly strengthen it, but rather is a behavior that is both desirable and topographically incompatible with the target behavior. The rationale is that the child cannot simultaneously engage in two incompatible behaviors, so as one is strengthened, the other must be weakened.

A DRI procedure could be used to intervene with a child who is continually out of his seat in the classroom. A desirable behavior that is topographically incompatible with roaming around the classroom is that of completing academic work. The teacher therefore could reduce the out-of-seat behavior by systematically reinforcing the child for completion of work. Another example of a behavior that could be treated with DRI is that of a young child who, while watching television, continually "twiddles" with her hair to the extent that bald patches are appearing. Such hair "twiddling" could be reduced by reinforcing the child for cuddling a teddy bear.

The big advantage of DRI is that the focus is on doing something positive, and not simply the removal of an unwanted behavior. It is for this reason that DRI is sometimes referred to as a constructional approach to weakening behavior. One potential procedural difficulty with DRI is that it is not always easy to find an appropriate behavior that is topographically incompatible with the target behavior. Another potential difficulty is that the child must be able to engage in the incompatible behavior for all of the time he would normally engage in the target behavior. This is usually referred to as complying with the 100% rule. Reinforcing piano playing could be used to treat the preschool child who hits other children, but the child could not be expected to play the piano for the total time in attendance at preschool.

It is important to note that when using DRI, some thought must to be given to what will be done if the target behavior does occur. There will be a need for a systematic response to that occurrence. The options will include strategies such as extinction, timeout, and punishment, all of which are discussed below.

5.05.4.2.2 Differential reinforcement of alternative behavior

In a similar fashion to DRI, the differential reinforcement of alternate behavior, or DRA, is a procedure that weakens the target behavior by reinforcing some specific other behavior. This is sometimes referred to as ALT-R. In contrast to DRI, the other behavior in DRA is not topographically incompatible with the target behavior. It is technically possible for the child to simultaneously engage in both the target behavior and the behavior being reinforced, but the expectation is that the reinforcement available for the new behavior will be of such strength that it will be preferred over the target behavior.

DRA also has the advantage of being a constructional approach to behavior reduction, and avoids the DRI difficulty of having to identify a topographically incompatible behavior.

As with DRI, when using DRA the target behavior can occur, and some systematic method of responding needs to be planned for.

5.05.4.2.3 Differential reinforcement of other behavior

Like DRI and DRA, the differential reinforcement of other behavior, or DRO, is a reinforcement-based procedure. Unlike the other procedures which reinforce some specific other behavior, DRO involves the reinforcement of any other behavior, that is, any behavior other than the target behavior. In effect, the DRO procedure translates into reinforcement being delivered for the absence of the target behavior for a predetermined period of time. Sometimes DRO is referred to as omission training. If DRO was being used to treat an aggressive behavior such as hitting other children, reinforcement would be delivered to the child after a set period time during which the child refrained from hitting.

There are many procedural variations of DRO (Vollmer & Iwata, 1992). First, there can be variations in the DRO time interval. The selection of this time is somewhat arbitrary, but it needs to be short enough to give the child a reasonable chance of securing the reinforcement. The time interval can be fixed or variable, but most commonly it is fixed for ease of implementation. One method of selecting the time is to make it the mean of the time intervals elapsing between responses during the collection of baseline data. This has been termed the inter-response time (IRT). Often in the use of DRO, a short time interval is started with, but this is progressively increased in length over time. This procedure allows the gradual fading of the use of the reinforcement.

Another procedural variation is to do with what is termed interval resetting when the target behavior occurs. One option is to reset the clock at zero, so if the target behavior occurs after 2 minutes of a 3 minute interval, the child has to abstain from that behavior for a further 3 minutes before reinforcement is forthcoming. A second option is to allow the current interval to finish (with no reinforcement), and then require another full interval to elapse before reinforcement. In the case above, the child would have to wait 4 minutes for reinforcement. This second option has some advantages in settings such as classrooms where it is easier for a teacher to attend to a child at set times, for example every 15 minutes. A potential problem with this method of resetting is that a "smart" child who transgresses during a set interval may realize that there is effectively no penalty for further transgressions during the remainder of that period, and take advantage of this. The reset to zero approach can also encounter some difficulties with the smart child. Take, for example, a child on a DRO intervention for hitting other children. Immediately following the receipt of reinforcement for abstaining from hitting, she may realize that now is the time to "get in a few good ones," as the effect of this is to delay the next reinforcement for only a few seconds. Clinicians have combated this by making the reinforcement available after successive intervals free of target behavior greater than that available after just one interval.

A final point in regard to the use of DRO, just as is the case with DRI and DRA, is that the target behavior can occur when using DRO, and some systematic method of responding (e.g., extinction, timeout, punishment) needs to be planned for.

5.05.4.2.4 Extinction

Extinction as a weakening procedure in clinical settings is based directly on the operant conditioning principle that a behavior which is never reinforced will decrease in frequency. It relies on the successful identification, during the functional assessment of the target behavior, of the reinforcers that are maintaining that behavior. Once identified, the contingent delivery of the reinforcers is stopped, and the behavior will eventually disappear.

On the face of it, extinction appears to be a straightforward procedure to implement. However, there are many procedural difficulties that need to be considered in developing an extinction-based intervention. First, extinction can only be used for behaviors that are extrinsically reinforced. It is simply not possible to remove intrinsic reinforcement. Unfortunately, many undesirable behaviors of children and adolescents are engaged in because they are fun.

The second procedural problem is related to the fact that the implementation of an extinction procedure is often followed by a rapid escalation in the target behavior, aptly called the extinction burst, before the behavior eventually weakens. It is critical that this burst is able to be tolerated. If extinction was being used to reduce the self-injurious behavior of a developmentally disabled child, considerable damage could be caused during the burst, making extinction a contraindicated treatment. Similarly, although extinction is very effective in treating night-time crying of children, there are some parents who become so anxious during the burst that the treatment is aborted.

A third procedural problem associated with extinction results from the fact that a given target behavior might be maintained by several reinforcers. If extinction is to be effective, all sources of reinforcement must be terminated. Take, for example, the situation where the target behavior is that of a preschool child hitting other children. The functional analysis of this behavior might show, *inter alia*, that this happens when the child wants a toy from the second child, and that the hit results in the toy being given up, hence reinforcing the behavior. A hastily conceived extinction program could dictate that whenever this happens the preschool teacher should admonish the offender and return the toy to the second child, hence cutting off that source of reinforcement. It might be, however, that the offending child finds adult attention to be very reinforcing, and this will still be readily available when an aggressive incident takes place. Additionally, incidents such as these attract attention from other children, which is also potentially reinforcing. To be effective, an extinction program needs to remove all sources of reinforcement from the target behavior. Some, such as teacher attention, might be relatively easy to remove, whereas others, for example, peer attention, can be more of a problem.

The final procedural problem associated with extinction is that the source of reinforcement needs to be removed on all, not just some or even most, of the occasions on which the behavior occurs. We know from basic operant conditioning principles that behaviors can be maintained on very thin schedules of reinforcement, particularly if the schedule is variable. Consider the parents who deems that their attention is maintaining the tantrums being engaged in by their toddler. They decide to use extinction to remove the tantrums, and ignore them for almost all of the time. Occasionally, they are a little stressed, cannot ignore the child's behavior, and pay attention to him. Here the parents have in fact placed the child, not on an extinction schedule, but on a thin variable schedule of reinforcement. Sadly, as is also know from operant principles, such a schedule makes behavior resistant to extinction.

5.05.4.2.5 Timeout

Timeout is perhaps the most misunderstood concept in ABA. Technically it refers to time out from reinforcement, literally meaning that reinforcement is not available for any behavior. Given that it is probably impossible to create an environment that is totally devoid of all sources of reinforcement, the term "timeout" is used to refer to the situation in which the reinforcement available in the environment is reduced whenever the target behavior occurs. The reduction is usually for a relatively brief period of time such as a few minutes. The contingent use of timeout leads to a weakening of the target behavior.

Frequently, timeout is taken to mean removal of the child from the environment she is in to another environment. If the new environment has less reinforcement available than the former, then this is timeout. If, however, as is often the case, the new environment has more reinforcement available, it is not timeout. It is not uncommon for children in schools to be taken from their classrooms and placed in "timeout" in the corridor, perhaps outside the principal's office. Under these circumstances there is likely to be more reinforcement available in the corridor than in the classroom. For a start, aversive work requirements are removed. And other activities such as chatting to children moving through the corridor are available. Under these circumstances, the use of "timeout" is unlikely to weaken the target behavior. In reality, it is "timein," and likely to strengthen the target behavior.

There are several procedural variations of timeout. First, there is the distinction between exclusionary and nonexclusionary timeout. Exclusionary timeout refers to the actual removal of the child to another location which is less reinforcing. Nonexclusionary timeout refers to making the current environment less reinforcing. This can be done, for example, by stopping interaction with other people in the room, or restricting access to certain activities in the room, or even using a special timeout chair. As with exclusionary timeout, the period of time of implementation is brief.

The amount of minimum time that is associated with timeout varies with the clinician, although it is usually related to the age of children. One useful rule of thumb is to begin with 2 minutes for 2 year olds, and then add a minute for each year of age to 10 minutes.

An important issue to do with timeout is related to what the child is doing when the time period is up. Let us take the example of a 3 year old child who has been placed in exclusionary timeout, but screams, shouts, and bangs on the door for the entire 3 minutes. If he is then permitted to leave timeout, it is possible that screaming and shouting will be reinforced and be more likely to occur the next time the child is placed in timeout. This, of course, would be counterproductive, and most clinicians require a period of quiet time before timeout is terminated, resulting in the timeout period potentially being longer than the established minimum. The length of the extension varies from clinician to clinician, some require only 15 seconds of quiet time, while others require a period equivalent to the established minimum. In practice, while some children will initially engage in resistive behaviors, after a few systematic trials they learn that resistive behaviors simply increase the length of the timeout and are quickly dropped.

Timeout has clearly proven to be one of the more powerful ABA procedures, and is widely applicable. The major limitation to its use is the availability of a timeout environment. In terms of nonexclusionary timeout, it is sometimes difficult to make the current environment less reinforcing. For exclusionary timeout, it may be difficult to access a suitable venue. An additional potential problem with exclusionary timeout relates to the child refusing to go. A small child can be carried, but a child who is large compared to the adult might successfully resist. Problems such as these would be contraindicative of the use of timeout.

A final comment on exclusionary timeout relates to its use in settings where there are policies regarding seclusion of children. Clinicians need to be thoroughly familiar with such matters. Additionally, regardless of statutory requirements, ethical considerations demand that the timeout venue meets minimum standards of warmth, light, and physical comfort. It is also a good idea for a record to be kept of the frequency of use and duration of each application of timeout. Such records are important for demonstrating that timeout is being used as a therapeutic technique, and not just a method for isolating a difficult child.

5.05.4.2.6 Overcorrection

The use of overcorrection to weaken a target behavior typically involves two components, restitution and positive practice. The restitution component involves the child in making good any damage caused by the target behavior. The positive practice component involves the child in repeatedly practising an alternative, acceptable behavior. Consider the use of overcorrection to treat disruptive behavior of children in the classroom. On entering the classroom, the child rushes down the aisle, knocks books off desks as he goes, and finally launches at a seat, pushing it across the classroom. The restitution component of overcorrection would require the child to return the scattered books to their desks and replace the chair to its proper place. The positive practice component would then require the child to leave the classroom, enter in an orderly fashion, and sit gently on the chair. Typically, several repetitions of the positive practice component would be required.

Overcorrection has had extensive use in treating disruptive behaviors, particularly those of children with a developmental disability, although its popularity does seem to have waned in recent years. This could be due the fact that the positive practice trials often involved physically forcing the child to engage in the behavior, and this has been seen as being unnecessarily aversive.

5.05.4.2.7 Punishment

Punishment as a therapeutic procedure has had two separate forms, the first involving the contingent removal of a positive reinforcer and the second involving the contingent delivery of a negative reinforcer.

The removal of a positive reinforcer is often referred to as response cost. The reinforcer would typically be one that is naturally occurring in the child's environment. Many families, for example, routinely restrict access to television or a favorite toy as punishment for a misdemeanor. Such use of punishment has rarely been controversial, provided that the reinforcers removed are viewed as privileges and not rights.

The negative reinforcer used in the second type of punishment is usually referred to as an aversive stimulus, and the use of such punishment procedures has been quite controversial. The controversy has centered not so much on the efficacy of such punishment, as there are well-documented examples of its successful use with seemingly intransigent behaviors such as self-injurious behavior exhibited by some people with developmental disabilities, but on ethical grounds, and the objections focus on the issue of whether punishment is ever really necessary. This matter will be addressed again in the discussion of the principle of the least restrictive alternative.

5.05.4.2.8 The principle of the least restrictive alternative

The procedures discussed for weakening behavior have been described with a particular order in mind. First covered were the differential reinforcement procedures, where the emphasis is on weakening the target behavior by strengthening other behaviors. These are generally considered to be minimally restrictive or intrusive for the child involved. At the other end of the spectrum was punishment using aversive stimuli, clearly a very intrusive procedure. It is generally accepted that clinicians should use interventions that are as minimally restrictive as possible, and this is referred to as the application of the principle of the least restrictive alternative (Turnbull, 1981).

While there is agreement that this principle ought be adhered to, what there is not agreement about is whether it is necessary to use aversive procedures at all. Some argue that all problematic behavior can be successfully treated if procedures such as the differential reinforcement procedures are used well. Others argue that there are not yet enough data available to warrant this conclusion, particularly in regard to behaviors such as the chronic self-injury exhibited by some people with developmental disabilities. An excellent selection of papers on this topic are included in Repp and Singh (1990).

5.05.4.3 Complex Procedures for Changing Behavior

The procedures described above are relatively specific, and are designed for either strengthening or weakening particular target behaviors. Sometimes the clinician is faced with a situation in which more generalized behavior change is required. In such situations, more complex procedures for changing behavior are appropriate. Examples of these are token systems, behavioral contracting procedures, and problem solving training.

5.05.4.3.1 Token economies

A token economy is a specifically constructed system in which desirable behaviors are reinforced with tokens and undesirable behaviors are punished by loss of tokens. Periodically, tokens can be exchanged for back-up reinforcers. Detailed planning is necessary for the successful establishment of a token economy. Care needs to be taken to ensure that back-up reinforcers are only available through the system, and circumvention of the contingencies through theft is not possible.

5.05.4.3.2 Behavioral contracting

Behavioral contracting involves the entering of a formal agreement with the child about what behaviors are required of him and what reinforcers will be consequently available. Contracts are usually written, and need to be constructed with a careful eye to specificity. From a theoretical perspective, behavioral contracts are a particular example of establishing rule-governed behavior in the child (Martin & Pear, 1996).

5.05.4.3.3 Problem solving training

The aim of this overall process is not to solve a particular problem for the child but to teach a general strategy that can be implemented for a variety of presenting problems. To do this, however, problems must be dealt with on an individual basis. This procedure involves selecting an individual problem and directively leading the child through a series of steps to solve it. The steps followed typically include (i) specification of the problem, (ii) generation of possible courses of action, (iii) selection of a course of action, and (iv) trying out the selected option. When one problem has been successfully dealt with, others are handled in turn, but with the clinician playing a less directive role on each subsequent problem. From a theoretical perspective, problem solving training, like contracting, is related to the establishment of rule governed behavior (Martin & Pear, 1996). However, unlike in contracting where the rules are command rules in that the clinician controls the reinforcers, in problem solving training the rules are more advice rules as the clinician is unlikely to control the relevant reinforcers.

5.05.4.4 The Triadic Model in ABA with Children and Adolescents

As has been indicated, a fundamental tenet of ABA is that the environment plays a major role in the development and maintenance of all behavior. From a clinical perspective, the reinforcers and punishers that naturally occur in the environment are essential to the maintenance of the problem behaviors. For children, the major sources of these reinforcers and punishers are the significant adults in the child's environment, that is, people such as parents, teachers, or child care personnel. It is quite logical, therefore, that intervention for the clinical problems of children is mediated through these significant others. The systematic manipulation of reinforcers and/or punishers that must be implemented to change the child's behavior is effected by changing the behavior of these significant others. Hence, the application of ABA procedures with children is often referred to as the triadic model, as it involves three persons, that is, the clinician, the significant other, and the child (Herbert, 1991; Tharp & Wetzel, 1969).

The implication of this requirement to change the contingencies of the child's behavior by altering the adult's behavior is that the adult's behavior becomes the focus of the intervention. For example, noncompliance in young children is treated by teaching the parents to give clear instructions and to reinforce differentially child compliance (Forehand & McMahon, 1981). In these situations, the clinician must think about the ways in which the antecedents and consequences of the parents' behavior can be changed in order to alter that behavior. Modeling might be used to teach the parents new child management skills, and then social reinforcement used contingent upon applying these skills in the home.

5.05.5 RESEARCH FINDINGS

5.05.5.1 Efficacy

A trademark of ABA is the systematic collection of data on the behaviors that are targeted for change. These data are then graphed to display the impact of the intervention in changing the baseline rates of the behaviors. Time series research designs such as reversal designs and multiple baseline designs are typically used to examine the functional relationship between the intervention and the target behavior (Hersen & Barlow, 1984; Kazdin, 1982). While designs such as these have respectable internal validity and are necessary to demonstrate a functional relationship between the treatment and the observed changes in target behaviors, they are not always used in standard clinical practice. Most practitioners rely upon the simple AB (baseline–treatment) design, hopefully with some form of follow-up. While this design is weak in terms of internal validity in that other plausible hypotheses might be offered to account for the behavior change, it is much easier to implement in standard clinical settings. The design will tell the clinician if the behavior has changed in the desired direction, it is just that the clinician cannot be absolutely certain that the behavior change was caused by the intervention. While demonstrations of functional control can only be demonstrated in individual interventions by the better-quality designs, some authors (Harris & Jensen, 1985) have argued that several replications of AB designs will produce the same strength of evidence of functional control as the more elaborate designs.

Regardless of the type of design, the traditional method for determining the existence of a treatment effect was that of visually analyzing the graphs constructed from the data collection. However, some authors (e.g., Crosbie, 1993) have warned against possible errors with this method, and have argued for the use of time series statistical analyses.

One point that supporters of visual analysis of data have made is that a statistically significant change might occur in the occurrence of the target behavior, but that the change might not be large enough to make a difference to the client's everyday functioning, that is, it might not be clinically significant. This issue of clinical significance of outcomes is part of a general construct that has become known as the social validity of the intervention (Kazdin, 1977; Wolf, 1978). Social validity is considered to have three components. The first of these is the social significance of the goals of the intervention, that is, have the right behaviors been selected as targets of change. The second is the social appropriateness of the intervention strategies, that is, if they are socially acceptable. The third is the social importance of the outcomes, that is, if the outcomes are clinically significant.

Notwithstanding the debate about the relative merits of visual and statistical analysis of data, ABA has been used either exclusively or in combination with other procedures to treat a broad range of clinical problems of children. These have included both externalizing disorders such as conduct disorders (Kazdin, 1987) and attention deficit hyperactivity disorder (Barkley, 1990), and internalizing disorders such as anxiety disorders (Siegel & Ridley-Johnson, 1985) and depression (Kazdin, 1990).

One matter that has received substantial attention in the use of ABA is the extent to which clinical effects are generalized. In order to examine generalization more fully, Drabman, Hammer, and Rosenbaum (1979) developed what they referred to as the generalization map. First, they discriminated among four basic types of generalization, namely generalization across settings, behaviors, subjects, and time. Setting generalization was considered to have occurred if there was change in the target behavior in a setting other than the one in which it was treated. Behavior generalization was considered to have occurred if a behavior not targeted changed along with the target behavior. Subject generalization was said to have occurred if the target behavior changed in an individual other than the child on whom treatment was focused. Finally, time generalization was said to have occurred if a change effected in the target behavior was still in place at a later time. In regard to generalization across time, a distinction is sometimes made between those occasions on which the treatment has been terminated and those on which it is still in place. Time generalization is used when the intervention has ceased, but the term maintenance is used if the treatment is still in place.

Each of the four basic types of generalization could occur alone or in combination with another. For example, generalization across settings and behavior would be said to occur when a nontargeted behavior changed in a setting other than the treatment setting. The four basic types can be combined in sets of two, three, or four to produce a map of 16 classes of generalization. Allen, Tarnowski, Simonian, Elliot, and Drabman (1991) reviewed 904 studies published in 28 journals over a 10 year period and found that only about half reported generalization data.

It may be the case that a lack of generalization is not a problem. Take the case of a child who exhibits problem behaviors in the home, but only at home. If an intervention strategy is put in place at home, and this successfully eliminates the behaviors, the issue of setting generalization is not relevant. If some form of generalization is required, however, it needs to be planned for. The intervention program should incorporate elements that promote the likelihood of generalization occurring. The need to actively program for generalization was initially called for by Stokes and Baer (1977), and more recently Stokes and Osnes (1989) presented a description of several programming tactics grouped into three general categories.

They described the first general category as the exploitation of current functional contingencies. This included tactics such as using naturally occurring reinforcers (and punishers) in the program. New behaviors may have to be taught, but, once learned, they will be maintained by the naturally occurring reinforcers. This will help with the fostering of time generalization. Another tactic in this category is to use naturally occurring reinforcers to systematically reinforce any examples of generalization that occur. If a child is on a program to improve behavior at home, reinforcement of better behavior at school by a teacher will promote setting generalization.

The second of Stokes and Osnes's categories was called training loosely. This refers to designing intervention programs that may begin by being tightly constrained, but move over time to being more diverse. An important tactic in such training is the use of what is referred to as multiple exemplars. A child learning a concept such as dog will be better ably to correctly identify all dogs if taught using a large range of examples of a "dog." A child undergoing compliance training will display better generalized compliance if taught using a range of instruction types and is reinforced using a range of reinforcement types.

The third of Stokes and Osnes's categories was referred to as the incorporation of functional mediators. A good example of a tactic in this category is seen in social skills training programs for children and adolescents. To increase the probability that skills learned in a clinical setting will be implemented in the community, the child carries a cue card which prompts the critical elements of the response required for a particular social situation.

As was indicated earlier, ABA interventions with children typically involve the triadic model in that behavior change in the child is effected through behavior change in a significant adult in the child's environment. When thinking from within the framework of the triadic model, the issue of generalization is complex because consideration must be given not only to generalization of the child's behavior but also to that of the adult. Sanders and James (1983) identified types of generalization that were relevant to parent behavior when training parents to implement intervention programs with their children. They referred to these as generalization across settings, behaviors, children, and time. Generalization across settings refers to the parent's ability to use the child management skills learned in one setting (e.g., the clinic) in a second setting (e.g., the home). Generalization across behaviors refers to the ability of the parent to use skills learned for one child behavior with a second behavior of the child. Generalization across children refers to the ability of the parent to use skills learned for managing one child for the management of a second child. Generalization across time refers to the parent's ability to continue to use learned skills after the training program has been concluded. These types of generalization of parent behavior are clearly an extension of the types of generalization cited by Drabman et al. (1979) in relation to child behavior.

Within the triadic model of treating children's clinical problems, it must be remembered that generalization of the behavior of the significant other in the child's environment must be planned for. The suggestions offered by Stokes and Osnes (1989) for promotion of generalization apply equally to the behavior of the adults as they do to the children who are the target of intervention. Sanders and Dadds (1993) provide an excellent set of suggestions for promoting the generalization of skills learned by parents in child management training programs.

5.05.5.2 Effectiveness

A distinction between efficacy and effectiveness is offered by Hoagwood, Hibbs, Brent, and Jensen (1995). Efficacy is considered to have been demonstrated when positive results are found in tightly controlled clinical trials. Effectiveness, however, is only demonstrated when efficacious procedures are successfully implemented with heterogeneous samples in natural settings (health clinics, homes, or schools) by practitioners other than research therapists. To assist in attempts to move from studies of efficacy to studies of effectiveness, Hoagwood et al. propose a three dimensional model, with the dimensions being labelled validity, intervention, and outcome.

For increased external validity, researchers are encouraged to conduct efficacy studies in more naturalistic settings. Because a fundamental premise of ABA is that the environment is a major determinant of behavior, most ABA interventions do occur in homes, or schools, and, as such, many of the reported studies already meet this requirement. The treatment of the presenting problem in the venue in which it occurs reduces the need to build in procedures for generalization across settings. Additionally, most ABA interventions with children involve the triadic model in which a significant other in the child's environment (parent or teacher) actually implements the intervention program. This training of the significant other to do this adds further to the validity of the intervention.

For improved performance on the outcome dimension, researchers are encouraged to broaden the range of outcome measures to include variables other than defining symptoms. ABA practitioners have taken substantial steps in this regard with the search for improved generalization across behaviors, and hence a variety of areas of child functioning are measured. Also, in a desire to achieve social validity of interventions, practitioners are assessing aspects such as consumer satisfaction with the outcomes of intervention.

For improved performance on the intervention dimension, researchers are urged to use less highly structured and manualized interventions to allow more access by practitioners in the field. However, as indicated by Hoagwood et al. (1995), care needs to be taken not to sacrifice treatment integrity. The move from high to low structure without loss of treatment integrity can only be achieved with highly trained practitioners. As indicated earlier, a thorough knowledge of the principles and procedures of ABA are necessary if a practitioner is to successfully implement, and potentially "trouble shoot," intervention programs.

5.05.6 FUTURE DIRECTIONS FOR RESEARCH AND PRACTICE

ABA is now well accepted as a sound model for the treatment of the clinical problems of children and adolescents. As was mentioned earlier, generalization of behavior change was a major issue in ABA. The acceptance of the need to actively program for generalization and the development of tactics for this (Stokes & Baer, 1977; Stokes & Osnes, 1989; Sulzer-Azaroff & Mayer, 1991) has made it less of an issue. Where to from here? While efficacious and effective treatment models are important, it would be generally accepted that prevention of clinical problems is always a better option than cure. It is in the sphere of prevention that ABA has much to offer.

Caplan's (1964) distinction among primary, secondary, and tertiary prevention of mental health problems is useful for a discussion of a future role of ABA. Primary prevention is absolute prevention as commonly understood. Secondary prevention refers to early identification of a problem and intervening in a manner to restrict development of it and to ameliorate any long-term effects. Tertiary prevention is intervention with fully developed mental health problems. Most of the applications of ABA up to 1997 have been in the realm of tertiary prevention. A child presents with a clinical problem and an ABA intervention is developed and implemented. There have been some excellent examples of ABA being used in secondary prevention. The work of Lovaas with autistic children is very relevant here. The long-term intensive use of ABA with young children diagnosed as autistic led to improvement in all of them, some to the extent that they could not be discriminated from typically developing children (McEachin, Smith, & Lovaas, 1993).

Researchers such as Loeber (1990, 1991) have studied the developmental pathways of conduct disorders and have identified the key risk factors associated with the development of such disorders. FAST Track is a long-term program aimed at providing intensive family- and school-based interventions for young children identified as being at risk for the development of conduct disorder (Conduct Problems Research Group, 1992; McMahon et al., 1995). It is a multicomponent program being implemented in four different locations in the USA and involves 500 high-risk children in elementary school. In addition, there are 800 high-risk or normal comparison children. All children are followed through eight years of school.

The real challenge is to have the principles and procedures of ABA adopted in mainstream family, health, and educational services with a view to the promotion of sound mental health. A useful model for conceptualizing interventions with families has been provided by Sanders and Dadds (1993), who identify five levels of intervention in families. These are described as (i) written advice only, (ii) written advice plus minimal therapist contact, (iii) written advice plus active parent training, (iv) intensive behavioral parent training, and (v) behavioral family intervention. These levels reflect differing intensities of intervention. The parent training referred to is the behavioral parent training that has been used extensively and successfully (Forehand & McMahon, 1981; Sanders & Dadds, 1993). At level (iii) it is relatively focused and helps parents manage specific problems with their children. At level (iv) it is more general and helps parents deal with a broader range of presenting problems. At level (v), the behavioral family intervention includes the training of level (iv), but addresses other matters such as marital problems or parental anxiety or depression. The interventions of levels (iii)–(v) are conducted by mental health specialists, and are examples of Caplan's tertiary prevention procedures. Interventions at levels (i) and (ii), however, are much closer to primary and secondary prevention.

Work by Sanders and his colleagues at the University of Queensland in Australia involves the development of an extensive range of written material that is available to families via level (i) and (ii) interventions. The materials, known as "tip sheets," provide advice to parents on fostering healthy development in their children. The tip sheets focus on specific parenting issues such as the management of feeding, sleeping, and compliance problems in their children. They are available to the public through a wide variety of primary care service agencies such as child health nurses, local doctors, and kindergartens. The advice given in the tip sheets is based on extensive empirical research.

The development of broad-scale, community-based, preventative interventions, such as those being developed by Sanders, is the challenge for the future use of ABA with children and adolescents.

5.05.7 SUMMARY

Clinical interventions based on the ABA approach have their roots in learning theory, particularly operant conditioning. Clinical problems are conceptualized as specific behaviors occurring too often (behavioral excesses) or too infrequently (behavioral deficits). The focus of intervention is on increasing behavioral deficits or weakening behavioral excesses. This is effected by manipulation of the antecedents and consequences that are functionally associated with those behaviors.

An important feature of ABA is its strong commitment to systematic data collection and evaluation of the success of interventions. A corollary of this commitment to data-based evaluation is that ABA is a hypothesis-testing approach. Once a target behavior has been identified for change, a hypothesis is formulated about the antecedents and consequences that are functionally related to the behavior. If success in not achieved by a manipulation of these antecedents and consequences, a new hypothesis needs to be considered.

Interventions derived from ABA have been used for the successful treatment of a range of clinical problems of children and adolescents. Early applications were in the field of mental retardation, but there is now a substantial record of success in the use of ABA for treating the broad spectrum of externalizing and internalizing disorders.

The challenge for the future use of ABA is in the realm of prevention. The learning principles which form the foundation of ABA apply to all children. The opportunity is at hand, therefore, to use these principles to construct community-based programs that either prevent the development of clinical problems (primary prevention), or that involve the early identification and treatment of clinical problems before they become major difficulties (secondary prevention).

ACKNOWLEDGMENTS

Thank you to my colleagues Jay Birnbrauer, Jan Matthews, and Roger Miller for their valuable comments on an early draft of this chapter.

5.06.1 THEORETICAL UNDERPINNINGS

Cognitive-behavioral therapy (CBT) with children and adolescents, relative to other theoretical approaches to psychological therapy, is a young but quickly developing area of clinical psychology. In a survey published in 1982, it was found that 40% of the new faculty in clinical psychology programs approved by the American Psychological Assoication identified themselves as cognitive-behaviorally oriented with an additional 18% identifying themselves as behaviorally oriented (Kleges, Sanchez, & Stanton, 1982). The combination of these two groups represents a majority of those surveyed. Given this presence in the training programs for the field, it is reasonable to expect that this orientation will continue to flourish and expand in the future. More importantly, however, the continued development of CBT in children and adolescents will be determined by evaluation of outcomes applied to the wide variety of psychological problems in youth (e.g., Kendall, 1991).

The achievements of CBT may be attributed to an intelligent integration of several theoretical perspectives: most notably, learning theory (behavior therapy) and cognitive theory (and therapy). CBT combines the paradigms of learning theory with an understanding of, and attention, to the cognitive activities of the client. Greatest emphasis is placed on the learning process and the influence of contingencies and models in the environment, while still reserving a central role for the individual's mediating/information processing style in understanding the development and remediation of psychological distress (Kendall, 1985).

5.06.1.1 Key Features of CBT

In addition to defining CBT as a rational integration of behavioral and cognitive theories and therapies, it may also be useful to distinguish this approach from others by examining its key features. Following a cognitive prototypes construct (e.g., Rosch, 1973, 1975) from experimental cognitive psychology, the degree to which a category member is "related" to the category in general depends on the number of features that the member shares with the category. In this case, given a list, such as the one below, of potential features of the cognitive-behavioral (CB) approach, one can determine the degree to which one would classify any given example as cognitive-behaviorally oriented. Aside from the first two features listed, none of the other elements is required for an intervention to be considered cognitive-behavioral. The first two features in the following list from Ingram, Kendall, and Chen (1991) represent core characteristics of the approach.

(i) Cognitive variables are assumed to be important causal and maintaining mechanisms. This statement does not rule out that other causal mechanisms may be operating as well, but rather that cognitive variables are important in conceptualizing the onset and course of a disorder.

(ii) Given that cognitive variables can be causal and maintaining agents, at least some of the treatment methods and strategies are aimed at cognitive targets.

(iii) A functional analysis of the variables maintaining the disorder is undertaken. This analysis may include examination of cognitive, behavioral and affective variables.

(iv) Both cognitive and behavioral therapeutic strategies are employed. As evidenced by Beck's (Beck, Rush, Shaw, & Emery, 1979) approach to the treatment of adult depression, as well as Stark and Kendall's (1996) approach with depressed youth, this combination may involve using behavioral strategies to target cognitive objectives as well as cognitive strategies to effect behavioral change.

(v) Empirical verification is sought and emphasized in at least three different ways. First, empirical research is used to examine the effects of the therapeutic procedures and to study the causal mechanisms of the changes observed. Second, the use of objective assessment during therapy provides a means of assessing therapeutic progress. Third, clients are taught how to gather data to test their assumptions and/or beliefs.

(vi) Typically, interventions are time-limited. Booster and maintenance sessions may be applied as necessary.

(vii) The client and therapist operate in a collaborative relationship, working together toward the goal of alleviating dysfunctional thinking and behavior.

(viii) CB therapists are active and offer to help evaluate suggestions rather than being passive and nondirective.

(ix) Educating the client about the CB model of dysfunction, the role of their thinking in the maintenance of dysfunction, and the need to modify dysfunctional cognition and behavior is deemed important.

(x) CB therapists serve as coping models, providing demonstrations in role-plays of ways to manage dysfunction and different situations.

A few words on what CBT is not. Unlike the psychodynamic perspective which concerns itself in part with efforts to uncover unconscious early experiences and trauma, CBT focuses more on the present, but acknowledges that early experiences are influential in learning behavior patterns and cognitive styles. Similarly, CBT does not focus on biological, neurological, or genetic aspects although again it acknowledges that they play a role, to varying degrees, in several disorders.

5.06.1.2 Behavior and Cognition in Context

Although it is clear from the listed features that CBT places major emphasis on both the learning process and mediating/information-processing factors, CBT also considers the relationship of cognition and behavior to affective state and functioning in the larger social context. This aspect of CBT is especially important in the treatment of children and adolescents because of the centrality of the social context in the developmental trajectory of children. Specifically, adequate relations with peers is a crucial component of successful adjustment, and consequently an approach which is sensitive to these issues both during the assessment and intervention phases of treatment is favored.

Equally, if not more, important, in considering children in context, is an understanding of the family. Many of the rules and roles for later social interaction are first introduced in this social microcosm. Consideration of the modeling and reinforcement practices parents use with their child can provide clues to the therapist about factors that may be maintaining the targeted behavior. For example, a parent who has perfectionistic expectations of their child, and who only rewards the child for flawless performance, may be a contributing factor in the maintenance of the child's anxiety in testing situations or in the child's overly harsh criticisms of themselves. Additionally, parents may prove to be a valuable resource as diagnostic and therapeutic collaborators: first, by providing information about the nature of the problem as it manifests itself outside the clinic, and second, by reinforcing at home lessons taught and gains made in therapy.

5.06.1.3 The Nature of Cognition

Given the centrality of cognition, an account of CBT requires a discussion of the more detailed features of cognition: cognitive structures, cognitive content, cognitive processes, and cognitive products (Ingram & Kendall, 1986; Kendall, 1993; Kendall & Ingram, 1987, 1989). Cognitive structures can be thought of as mental templates that are based on an accumulation of experiences in memory which act to guide and filter the understanding of new experiences. Cognitive content refers to ongoing self-talk, as well as the information that is stored and organized in memory. Self-talk or internal speech are examples of surface cognitive content. Cognitive structures serve to trigger automatic cognitive content and information processing. Cognitive processes are the procedures by which the cognitive system operates—how we go about perceiving, recalling, and interpreting experience. Search and storage mechanisms and inferential and retrieval processes are examples of cognitive processes. Cognitive products are the end result of the operations of the system. These are the thoughts that an individual experiences as a result of the interacting content, process, and structure, and can be illustrated by causal attributions

Psychopathology (and psychological therapy) may be related to problems (and corrections) in any or all of the above areas of cognition, and the understanding of specific disorders and their treatment benefits from consideration of each of these factors for each client. For example, an anxiety-disordered youth who has a schema for threat (cognitive structure) about danger (evaluative and physical) would have automatic thoughts (questions) and an internal dialogue (cognitive content) that would be consistent with that schema (worry). The cognitive process that this individual engaged in would be influenced by the cognitive structures and would therefore be likely to consist of selective attention to cues for evaluation and risks of negative outcomes. Consequently, the individual would be predisposed to see danger in events and to hold demanding expectancies about the future.

Cognition can be divided further. Just as child behavior disorders can be broken down into internalizing and externalizing varieties where internalizing behavioral disorders involve problems within the self and externalizing disorders pertain to conflict with the outside world (Achenbach, 1906), so too can dysfunctional cognitions be subdivided. Two separate categories for cognitive dysfunctions have been described (Kendall, 1985, 1993): cognitive deficiencies and cognitive distortions. Deficiencies refers to an absence of thinking where it would be beneficial (i.e., acting before thinking). Children and adolescents with these deficits in information processing fail to engage in forethought and planning. Conversely, children and adolescents who have distorted cognition are not failing to engage in information processing but are rather doing so in a dysfunctional, "crooked" manner. On a historical note, the distinction between deficient and distorted cognition highlights the differences between the forerunners of adult CBT which focused primarily on distorted thinking, and early child CBT which was mainly intent upon remediation of cognitive deficits in children (Kendall, 1977; Meichenbaum & Goodman, 1971).

Although the distinction between distorted and deficient cognition often runs parallel to the distinction between internalizing and externalizing behavior (i.e., disorders associated with distorted cognition also tend to be associated with internalizing behavior, anxiety, and depression; and deficient cognition with externalizing disorders, attention-deficit hyperactivity disorder (ADHD), tend to group together), the associations are not perfect (Kendall & MacDonald, 1993). For example, aggressive behavior (externalizing) entails cognitive deficiencies and cognitive distortions (e.g., Dodge, 1980; Dodge & Frame, 1982; Lochman, 1987).

Some consider the frontier in current CBT conceptualizations of cognition to be the constructivist narrative. Proponents of this view (e.g., Epstein & Erskine, 1983; Guidano & Liotti, 1983; Harvey, Weber, & Orbach, 1990; Mahoney & Lyddon, 1988; McNamee & Gergen, 1992; Meichenbaum & Fitzpatrick, 1993; Neimeyer, 1993; Neimeyer & Feixas, 1990; White & Epston, 1990) see the human mind as a product of constructive symbolic activity and see reality as a product of personal meanings that individuals create. In contrast to a solely information-processing view of cognition, this perspective holds that there are many realities, and thus the distortion of a universal reality can no longer be seen as a viable metaphor for explaining the existence of psychopathology. This evolving CB approach maintains instead that some realities are more functional than others for given individuals in given circumstances. A goal of the therapist then becomes one of helping clients become aware of how they create their realities and the ensuing consequences of those constructions.

5.06.1.4 Developmental Sensitivity

CBT does *not* subscribe to what Kendall (1984) described as "the developmental uniformity myth." Rather, children are not homogeneous and CBT acknowledges that treatment may be differentially effective as a function of a child's developmental level. This developmental sensitivity also implies that each individual child is not "constant" from pre- to post-treatment. Relatedly, one must note that children with the same behaviors but of different ages are not necessarily alike. Avoiding the developmental uniformity myth means giving adequate consideration to age (age groups or developmental groups) as a potential moderator variable of treatment effects, and creating interventions which are intentionally geared specifically to the child's age or level of cognitive development. This issue is considered further in Sections 5.06.3 and 5.06.5.

5.06.1.5 Role(s) of the CB Therapist

Elsewhere, Kendall (1993) used the terms "consultant," "diagnostician," and "educator" to refer to the therapeutic posture of the therapist. As a consultant (collaborator), the therapist is viewed as having ideas worthy of trying but not as the one who has all of the answers. A goal is to give the client the opportunity to try new ways of thinking and behaving and to help them make sense of the experiences and the results. The therapist intentionally acts as a problem-solving model as one way of encouraging the client to become an independent and mature problem solver. As a diagnostician, the therapist integrates data gathered from many sources: synthesizing new information with knowledge about psychopathology, normal development, and psychologically healthy environments. The outcomes of this process are well reasoned decisions about the nature of the problem and the optimal strategy for its treatment. As an educator, the therapist attempts to present the information of therapy in a manner which facilitates the client's learning-specific behaviors, cognitive skills, and emotional development. Helping clients to think for themselves is an ultimate goal. Thinking for oneself may provide the maximum possibility for the generalization of skills learned in therapy to other problematic areas which may or may not be present at the time of treatment. In this way, although CBT is not aimed at providing a cure *per se* for a client's problems (Kendall, 1989), the changes produced by the intervention can be used in the management of psychopathology in areas beyond those where they were initially applied.

5.06.1.6 Realistic Goals for Therapy

In helping a client cope with problems (rather than striving to cure the problem), CBT provides the client with realistic expectations about potential outcomes. Psychological change is not linear, and lapses/relapses are likely. CBT prepares clients for the fact that booster sessions may be necessary and helps them view lapse in a constructive manner rather than as a failure. Implicit in this idea is the notion that all forms of psychopathology are not equally responsive to psychological interventions. This realistic appraisal helps the client and therapist focus on doable change that is likely to occur.

Although little written attention has been devoted to factors such as trust, respect, and relationship as part of the CBT process, this should not be taken as an indication that they are not important elements of this treatment. Our discussion has focused on elements of treatment that are specific to CBT and because those factors are essential elements of all forms of treatment, it was not deemed necessary to discuss them specifically here.

5.06.2 HISTORY OF THE APPROACH

Consideration of the origins of CBT is helpful in setting the current features of the approach in their proper context. However, all accounts of historical information can only represent a limited perspective on the events of the past. This account of the history of CBT with children was shaped in large part by the work of Meichenbaum (1995) and Meyers and Craighead (1984).

In some senses Witmer (1907) could be credited with the earliest example of contemporary behavior therapy. His psychological clinic, established in 1896, was the first of its kind. His interventions with childhood academic and mental health problems had many of the hallmarks of current CB approaches: they were directive, educational, based on principles from perception and learning, and empirically evaluated for effectiveness.

More traditional accounts of the birth of behavior therapy with children, however, usually begin with the work of Watson (1924) and his colleagues Rayner (Watson & Rayner, 1920) and Jones (1924a, 1924b). Together these pioneers in behavior therapy with children studied the effects of conditioning on the development and amelioration of fears. Somewhat later, although equally durable to the effects of time is the "bell-and-pad" procedure originally introduced by the Mowrers (Mowrer & Mowrer, 1938) for the treatment of enuresis.

These early endeavors were all but ignored until the 1960s, however, due to the prevalence of the psychoanalytic treatment of psychological problems at that time. When the psychoanalytic era waned, it was Rogers' (1951) client-centered therapy which emerged as an approach that was especially embraced by school psychologists. By the late 1950s and early 1960s, most psychologists, psychiatrists, social workers, and school psychologists were either using psychoanalytic or client-centered techniques with their child clients.

The therapeutic effectiveness of the prevailing approaches began to be questioned: in child-clinical circles, the critiques of psychodynamic psychotherapy (Levitt, 1957, 1963) were based on the lack of data to support the effectiveness of the psychodynamic approach. Early inroads by behavior therapists were seen in the treatment of severely disordered children. Perhaps because of the level of difficulty associated with treating these clients with the traditional methods of the time and perhaps because of the appropriateness of the behavioral approach, these early applications of behavior therapy to clinical cases were welcomed and successful. The majority of clinical applications of behavioral principles during this time focused on the application of operant procedures, with some ancillary use of modeling and systematic desensitization used specifically for anxiety and phobic disorders.

Fueled by empirical literature, clinical behaviorism took hold. The potential to predict and modify abnormal behavior through the study of the stimulus–response links thought to account for its occurrence created much excitement and anticipation in the field. The boom of behavior therapy was further bolstered by the creation of several scholarly journals (e.g., the *Journal of Applied Behavior Analysis*, created in 1968) and professional associations which specialized in behavior therapy and applied behavior analysis (e.g., the Association for the Advancement of Behavior Therapy).

Experimental and developmental psychologists were among the first to reconsider cognitive constructs and models as possible moderators of behavior. Clinical and social psychology also began to incorporate theories of cognition into what had previously been strictly behavioral models. Although the shift away from strict behavior therapy toward cognitive behavior therapy was marked by more than a few bumps in the road, this process should be considered more of an evolution than a revolution (Meichenbaum, 1995). According to Meyers and Craighead (1984), the shift toward CBT with children was influenced by three primary factors: cognitive psychology, self-control clinical interventions, and cognitive therapy.

5.06.2.1 The Impact of Cognitive Psychology

Cognitive psychology influenced behavior therapy with children in several ways. First, social learning theorists (e.g., Bandura, 1969; Kanfer & Phillips, 1970; Mischel, 1973; Rotter, 1966) and others provided explanations of phenomena which had previously been explained solely by behavioral principles. Perhaps the most long-lived of these has been the account of modeling effects. Bandura suggested that in addition to being explained by the principles of learning, observational learning was also influenced by the processes of attention, retention, motor reproduction, and incentive and motivation. Not only was this expansion into cognitive concepts, such as attention and retention, innovative and groundbreaking in its own right, but it also set the stage for more flexible and expansive theorizing than was previously the case under strict behaviorism.

A second avenue of impact for cognitive psychology came from research findings on the inferential and decision-making processes of individuals (e.g. Kahnemann, Slovic, & Tversky, 1982; Nisbett & Ross, 1980; Tversky & Kahnemann, 1974). These researchers and others drew the field's attention to the fact that individuals are often biased, inefficient, and incompetent information processors, with poor decision-making abilities. They mounted evidence for the fact that decision making was often influenced by habits of thinking, or mental heuristics, rather than being based on real events. This information provided a much needed metaphor for understanding psychopathology from a cognitive perspective.

Problem-solving and coping skills interventions were developed to put findings from cognitive psychology to work in clinical practice (e.g., D'Zurilla, 1986; D'Zurilla & Goldfried, 1971; Meichenbaum, 1985; Spivack & Shure, 1974). Programs were designed to teach and evaluate social problem-solving thinking: alternative thinking—generating multiple potential solutions to interpersonal problems; means–end thinking—considering the step-by-step process necessary to reach a desired goal; and, consequential thinking—focusing on the consequences that occur as a result of choosing a particular behavioral response (Spivak & Shure, 1974). The early success in teaching children problem-solving skills has led to much work in this area.

Based on the work of the cognitive developmental psychologists Vygotsky (1978) and Luria (1976), Meichenbaum and Goodman (1971) developed a self-instruction program to teach impulsive children how to control their behavior. Vygotsky and Luria suggested that during development, children's behavior is first under the verbal control of the social environment (most often by adults), and then gradually under personal control through overt speech and then slowly through covert speech. Applying these principles, Meichenbaum and Goodman's procedure entailed having an experimenter model overt behavior and associated self-statements for the impulsive child. The success of this early trial of self-instruction training has led to its application in a wide variety of other child and some adult psychopathology fields (e.g., Craighead, Wilcoxon-Craighead, & Meyers, 1978; Kendall & Williams, 1981; Meichenbaum, 1977).

5.06.2.2 Self-control Clinical Interventions

Self-control interventions, like many other influences on strict behavior therapy, were originally explained by the same operant models which formed the core of behavior therapy. During the late 1960s, however, cognitive explanations for self-control procedures began to develop and to spark researchers to think about changing internal thought processes as a means of teaching the individual self-control (e.g. Mahoney, 1974; Kendall & Braswell, 1982; Kanfer & Karoly, 1972; Craighead, Brownell, & Horan, 1981).

5.06.2.3 Cognitive Therapy

Unlike self-control programs, cognitive therapy developed outside and separate from the realm of behavior therapy. Working almost exclusively in the clinic as opposed to in the laboratory, Ellis and Beck, two major leaders in the development of cognitive therapy, were separately developing interventions aimed specifically at altering maladaptive cognitive processes. Ellis' (1962) rational-emotive therapy focused on the idea that individuals behave maladaptively because of irrational and illogical thought processes. It is what individuals think about the things they say and do that has the potential to upset them. Beck's (1976) approach to cognitive therapy also saw maladaptive cognitions as a culprit in the etiology of psychopathology. Beck argued that these maladaptive thought processes were a reflection of an individual's assumptions and beliefs about themselves and the world. Cognitive therapy focuses on modifying the fundamental assumptions and beliefs on which the maladaptive thoughts are based. In both cases, the success of these approaches in treating adults has greatly influenced the development of CBT.

5.06.3 ASSESSMENT AND CLINICAL FORMULATION OF THIS APPROACH

CBT's approach to assessment has two foci. First, the assessment process is viewed as a hypothesis-testing endeavor. These hypotheses then guide the process of understanding a given child in their social context so that appropriate treatment strategies can be implemented to ameliorate the child's current difficulties (Ollendick & Hersen, 1993). Unlike more traditional assessment methods which are focused on searching for underlying personality characteristics or traits that are assumed to be causal factors in current distress, the hypothesis-generating process places primary importance on clearly describing current behavior, thought patterns, affective understanding, and environmental conditions which are thought to be related to the presence and maintenance of the child or adolescent's distress. Also, in contrast to traditional assessment techniques, CBT assessment strives to take a sampling as opposed to a symbolic approach to choosing and interpreting the results of testing. That is to say, CBT assessment techniques, being based on observable behaviors and reliably measured cognitive and environmental variables require little inferential work. More traditional assessment procedures, in contrast, rely on viewing the testing results as an indirect manifestation of underlying personality traits which are thought to be causing the presenting problems. Accurate sampling of behavior and cognition which are similar if not identical to the behavior and cognition which are targeted by the intervention is therefore a cornerstone of the CB assessment process.

Second, CBT views the assessment process as a means of evaluating the effectiveness of specific intervention procedures. Given the importance CBT places on the empirical evaluation of its treatment procedures, this is an essential part of the assessment process. Being able to report that a given behavior or cognition changes from pretreatment to post-treatment requires careful measurement of these elements at both time periods. Establishing that the observed changes are due to the intervention and not to some other confounding variable, however, requires additional consideration and controls.

5.06.3.1 Developmental Sensitivity Revisited

In child and adolescent treatment, a potential threat to the internal validity of the treatment is the effects of maturation. Children and adolescents are changing organisms who may simply "grow out of" their original presenting problems. To assert that the observed changes from pre- to post-treatment are due to the intervention and not to maturation, one must not only accurately measure the target constructs at pre- and post-treatment, but one must also know what norms are appropriate for comparison purposes at each time. The norms used prior to treatment may no longer be appropriate following treatment. CBT assessment procedures strive to be developmentally sensitive by using age-appropriate data on which decisions about the efficacy of treatment will be based.

A method for treatment evaluation might be to use the "normative comparisons" approach to clinical significance (Kendall & Grove, 1988). In addition to using statistically significant changes as a barometer of effectiveness, this approach also evaluates interventions based on the child's level of functioning in comparison to a meaningful and representative nondisturbed reference group. Because of maturational factors, it is essential that normative reference groups match clients on age. When a client, after statistically meaningful treatment effects, has returned to symptom levels indistinguishable from normals, then the normative comparison method can be said to have provided evidence of clinically significant change.

CBT assessments are geared to be developmentally sensitive because, in deciding if treatment is needed for a given problem or in deciding what aspects of a child's presenting picture are outside of the normal range, a clinician needs to be aware of the appropriate group with which to compare a child's behavior and cognition. For example, it is more acceptable for a six-year-old to exhibit mild features of separation anxiety than for a 14-year-old to exhibit the same pattern.

A further challenge to the accurate assessment of children and adolescents is that manifested symptoms of a given disorder may vary with developmental level. This complicates the diagnostic picture for youth because the behavior and cognition targeted by a certain intervention may vary and other symptoms of the same problem may take their place. It is analogous to trying to hit a moving target. For instance, Strauss, Lease, Last, and Francis (1988) reported that the American Psychiatric Association's *Diagnostic and statistical manual of mental disorders (third edition, revised) (DSM-III-R)* category of overanxious disorder was most often typified by unrealistic worry about the appropriateness of past behavior and comorbidity with major depression and simple phobia in children and adolescents aged 12–19; in contrast, in children aged 5–11 this type of worry was often not endorsed and comorbidity was more often seen with separation anxiety and ADHD.

It is somewhat unclear whether the observed differences in symptom manifestation across developmental levels are due to changes in comprehension and/or expression abilities or in some other factor which changes with developmental stage. This being so, it is important for classification systems used to diagnose children to be sensitive to these issues. For this reason, among others, the practice of simply scaling down adult syndromes to be applied to youth is not considered appropriate or desirable. While our current system of classifying childhood psychopathology takes into account the fact that children possess the same capacities as adults in terms of: influencing others through social interaction; processing and interpreting information in their environments; and, making choices that shape their worlds; it has also evolved to include specific diagnostic categories which may be unique to childhood, and may be more congruent with how a child or adolescent would present with a given difficulty. Diagnostic systems need to continue to develop as more data about the reliability and validity of the childhood diagnostic categories become available (Callahan, Panichelli-Mindel, & Kendall, 1996).

The challenge of collecting assessment data from children and adolescents is formidable. One facet of this issue is that assessment instruments are created by adults, and although some progress has been made in developing assessment tools that are geared for younger clients, this is still an area in need of attention. For example, a very common way of assessing the degree to which someone experiences a specific symptom is through a rating scale with approximately five anchor points ranging from "never" to "always." Evans and Nelson (1986) presented data that call into question a young child's ability to make the fine-grain distinctions which are required by these five-point scales. Some investigators (e.g., Finch & Montgomery, 1973; Sheslow, Bondy, & Nelson, 1982) have used pictorial assessment instruments instead of verbal ones to address this problem.

To increase the likelihood of obtaining assessment data that is reliable and valid, CB theorists agree with the suggestion to use multiple modes of assessment. Typically, paper-and-pencil questionnaires, structured interviews, and behavioral observations are cornerstones of CB assessments. No single approach perfectly captures the complexity that is involved in developing a case profile for a child or an adolescent, but the hope is that through using multiple methods one can begin to triangulate on the truth. It is important to emphasize, however, that this combination of assessment modalities is only as strong as its weakest link, and therefore the compilation of multiple methods does not excuse the assessor from considering reliability and validity data for each assessment tool used.

Another consideration when attempting to formulate a treatment plan for a child or adolescent is that youth rarely refer themselves for treatment. Usually a concerned adult (teacher, parent, or other adult figure in the child's life) brings the child to treatment. This may mean that the child or adolescent does not acknowledge that they have a problem requiring treatment and either from obstinacy or ignorance may not be able to provide the assessor with enough information on which to formulate the case. With some disorders, the child or adolescent's inability to provide the needed information may be directly related to the presenting problem. For example, an anxious child with perfectionism and need for social acceptance may be especially apprehensive about sharing their problems with the assessor because of a fear of being perceived negatively.

For the parent or referring adult's part as well, there may be reasons not to rely solely on the information provided. For instance, consistent with Harris and Ferrari (1983), it has been speculated that parents cannot consistently evaluate their child's behavior objectively; they may hold distorted perceptions and/or unrealistic expectations for their child. This inaccuracy may be related to something as simple as unfamiliarity with what is appropriate behavior for children of certain ages or it may be related to issues and problems that the parent is experiencing. CB theorists do not believe that a child's behavior is entirely caused by underlying personality traits that are constant across situations, so it also stands to reason that a parent or teacher who is observing a child in only a limited number of environments could not be expected to provide complete information about the nature of a child's difficulties. Therefore, whether through lack of information or inappropriate expectations, assessment of children and adolescents is best when drawn from many sources. Typically these include self-, parent-, and teacher-reports, and shared experiences with the therapist.

5.06.4 THE EFFICACY AND EFFECTIVENESS OF COGNITIVE-BEHAVIORAL TREATMENTS

Two terms have appeared for evaluating a treatment's success: efficacy and effectiveness. Efficacy and effectiveness studies can be distinguished by the amount of control exerted by the experimenter in the study. Hoagwood, Hibbs, Brent, and Jensen (1995, p. 683) defined efficacy studies as those in which "considerable control has been exercised by the investigator over sample selection (usually recruited samples), over delivery of the intervention, and over the conditions under which the intervention or treatment occurred." The typical example of an efficacy study is a randomized clinical trial in a structured university clinic setting. An intervention's effectiveness is typically tested using a more heterogeneous sample of clients or a more naturalistic setting (e.g., home, school, or more general medical setting), or by having treatment provided by real-world practitioners rather than research therapists (Hoagwood et al., 1995). The primary purpose of effectiveness studies is to evaluate how viable, or how transportable, an efficacious treatment is in real-world settings which often include a wide array of environmental factors that may impact treatment success.

Randomized clinical trials of psychological therapy for children and adolescents have been scant in comparison to studies of adults. Nevertheless, compared to other child treatment modalities, CBT is one of the more frequently and rigorously evaluated therapeutic interventions. In one study, analyzing the characteristics of child and adolescent research from 1970 to 1988, behavior modification was found to be the focus of 49.5% of all therapy studies and cognitive-behavioral approaches the focus of 22.1% (Kazdin, Bass, Ayers, & Rodgers, 1990). The majority of the studies surveyed were conducted in research-oriented clinics. Recently, the transportability of treatment from well-controlled research experimentation to more real-world practicing clinical settings has become a research question (Hoagwood et al., 1995; Kendall & Southam-Gerow, 1995). Among the differences between clinical research and clinical practice, clients seen in research settings are thought to present with a restricted range of disorders with less severe symptomatology (though this has not been the case in recent research), due to exclusion criteria set by the experimenter. Therapy in research clinics is also often conducted by specially trained therapists with small caseloads in well-controlled environments (Weisz, Weiss, & Donenberg, 1992). These differential specifications and conditions under which treatment is provided can be a source of concern when considering evaluations of treatment methods and processes.

A growing list of well-controlled therapy outcome studies has contributed to establishing the efficacy of CBT for children. CB interventions designed for children with depression have produced reductions in self-reports and clinical ratings of depressive symptoms in comparison to waitlist controls (Reynolds & Coats, 1986; Stark, Reynolds, & Kaslow, 1987), accompanied by reductions in anxiety and improvement in academic self-concept (Reynolds & Coats, 1986). Similarly, in a comparison of CBT with and without parental involvement, Lewinsohn et al. (1990) found that compared to a waitlist condition, both treatment conditions resulted in greater reductions in depressive symptomatology and percentage of clients meeting diagnostic criteria for major depressive disorder (MDD) (i.e., 57.1% of children in individual treatment, and 52.4% of individual plus parent treatment met criteria for depression at post-treatment, vs. 94.7% of waitlist). CBT has also demonstrated some superiority over traditional counseling modalities. For example, Stark, Rouse, and Livingston (1991), in a direct comparison of CBT to a traditional counseling program (duration of 24–26 sessions), found that CBT led to greater improvements in depression and reductions in depressive thinking (see also Stark & Kendall, 1996; Stark et al., 1996).

With regard to long-term treatment effects for children with depression, treatment gains have been maintained over short-term follow-up periods of 5–8 weeks (Reynolds & Coats, 1986; Stark, Reynolds, & Kaslow, 1987). However, longer-term follow-up evaluations have yielded more inconsistent results. For example, Stark et al. (1991) noted that some treatment gains were not maintained at seven-month follow-up. Conversely, Lewinsohn et al. (1990) found that depressed adolescents who had received CBT treatment continued to show increased recovery rates over a 2-year follow-up period, with only 17% still meeting *DSM* criteria for MDD at 6, 12, and 24 months.

Cognitive-behavioral interventions with anxiety-disordered youth, a clinical population often overlooked because their behavior may be less disruptive than children with externalizing disorders, have received empirical support (Kendall, 1994; Kendall et al., in press). In comparison to an eight-week waitlist control, a 16-week CB intervention (see Kendall, Kane, Howard, & Siqueland, 1990) produced both statistically and clinically significant improvements on parent-, child-, and teacher-reported measures for 47 children diagnosed with a primary anxiety disorder (Kendall, 1994). These improvements were evident on measures of anxiety, internalizing behavior problems, and depressive symptomatology. Nearly two-thirds of participants no longer met diagnostic criteria for their primary anxiety disorder following treatment. Children participating in the CBT group showed clinically significant gains by returning to within nondeviant limits on many of these measures. Gains seen at post-treatment were also maintained at one-year (Kendall, 1994) and longer-term (3.35-year) follow-ups (Kendall & Southam-Gerow 1996). In a second randomized clinical trial, Kendall et al. (in press) replicated the efficacy of this protocol with 94 anxiety-disordered children. In addition to demonstrating similar treatment gains as the previous trial (Kendall, 1994), comorbid status was not shown to moderate outcome. The program was effective when applied with families (Howard & Kendall, 1996), and work done in Australia, using a modified version of this program (Barrett, Dadds, & Rapee, 1996), provides a cross-cultural and independent replication of favorable treatment outcomes.

CBT has been applied with children exhibiting aggression and antisocial behavior. In a randomized clinical trial of 112 children (aged 7–13) exhibiting antisocial behavior, Kazdin, Bass, Siegel, and Thomas (1989) found significantly greater therapeutic effects for two forms of CBT in comparison to relationship therapy (RT). The two CBT interventions were a problem-solving skills training (PSST) and a problem-solving skills training with *in vivo* practice (PSST-P). At post-treatment, outcome measures revealed significant treatment effects for parent-, teacher-, and child-completed measures. Although all three treatment groups led to some improvements over the course of treatment, the magnitude of the improvements and breadth across measures were greater for children in the PSST and PSST-P groups than for those in the RT group. The improvements of the two PSST groups were particularly superior to those of the RT group in the areas of prosocial measures (social competence and global adjustment) and on diverse scales that reflect problem behavior at school. In this study, the practice component appeared to enhance PSST. In another study (Kazdin, Siegel, & Bass 1992), a parent management component enhanced therapeutic effects over PSST in child and parent functioning and placed a greater proportion of youth within normative levels of functioning.

Other studies have found that CB therapeutic effects may lead to improvement in social-cognitive processes associated with aggressive behaviors (e.g., disciplining for fighting) or improvements in interpersonal skills, but may not lead to change on ratings on teacher reports (Baum, Clark, McCarthy, Sandler, & Carpenter, 1986; Kettlewell & Kausch, 1983; Lochman, White, & Wayland, 1991). The success of CBT in the treatment of aggressive youth is also tempered by difficulties with generalization of treatment effects and persistently elevated levels of disruptive behaviors in normative comparisons. For example, long-term follow-up assessments suggest that decreases in aggressive or delinquent behaviors are often not maintained over time (Kazdin, 1987; Kendall & Braswell, 1982; Lochman, 1992), or are not generalized across situations, for example, classroom behaviors (Baum et al., 1986; Lochman, Burch, Curry, & Lampson, 1984).

To aggregate findings across studies, researchers have used meta-analysis. Meta-analysis, with reference to therapy outcomes, provides a format for quantitatively assessing the effects of particular treatments across studies. In general, behavioral and CB therapies have compared favorably to other theoretical approaches. In meta-analyses including only controlled studies, the mean effect sizes for CBT have ranged from 0.56 to 0.81, for behavioral therapies (including studies of CBT) from 0.88 to 0.91, and for nonbehavioral therapies (including client-centered and psychodynamic therapies) from 0.40 to 0.44 (Casey & Berman, 1985; Durlak, Furhman, & Lampman, 1991; Weisz, Weiss, Alicke, & Klotz, 1987). In general, findings have supported the importance of the behavioral component of CBT (Durlak et al., 1991; Weisz et al., 1987). A meta-analysis that compared controlled outcome studies conducted in both research and practicing clinics found that only the use of behavioral interventions and the treatability of clients (severity of symptoms and presence of comorbidity) predicted treatment outcome (Weisz, Donenberg, Han, & Weiss, 1995).

One meta-analysis focused specifically on CBT. Durlak et al. (1991) reviewed 64 reports of controlled CBT studies conducted between the years of 1970 and 1987 involving children between the ages of five and 13. The overall effect size (ES) for CBT was 0.56. This overall ES represents a moderately beneficial treatment effect, but it should be noted that children who had reached the cognitive stage of formal operations (ages 11 to 13), displayed a large treatment effect (ES = 0.92) in response to CBT. The ES in older children was twice as large as that for children in less advanced cognitive stages (0.57 for ages five to seven; 0.55 for ages eight to 11). The analyses provided data that are consistent with two assumptions of CBT: first, that cognitive developmental level is a factor in a client's response to treatment; and second, that activating cognitive processes may be one of the specific treatment components of CBT.

Durlak et al.'s (1991) review also demonstrated that children undergoing CBT exhibited clinically meaningful gains. In studies comparing treated groups to normative samples, (see also normative comparisons; Kendall & Grove, 1988), treated children displayed clinically meaningful gains (i.e., changed from being beyond normal limits at pretest to being well within normal limits at post-treatment) on measures of personality functioning and cognitive tempo. Contrary to expectations, clinically significant changes were not obtained on behaviorally oriented measures in children who underwent treatment. Although scores on behavioral measurements did decrease in the predicted direction, they did not decrease enough to return youths to within normal ranges. In general, after age was taken into account, no other factors were significant in moderating treatment outcome.

A challenge facing "effectiveness" researchers is finding ways to employ interventions in a fashion that will reach wider populations without sacrificing treatment integrity. Clinical research has traditionally placed internal validity (the extent to which the treatment works) in a position of primary importance above external validity (a treatment's generalizability). This is not unreasonable because many interventions have yet to be empirically supported (Kazdin, 1988). Issues of internal and external validity are of interest to the effectiveness researcher.

Psychological treatment conducted with children in practicing-clinical settings has traditionally enjoyed less success than psychological interventions performed in research-based clinics (Weisz & Weiss, 1989). In Weisz et al.'s (1995) analysis of this discrepancy between research and clinical interventions, it was demonstrated that improvement differences could be accounted for by the use of behavioral interventions and the relative treatability of the client population (severity of symptoms, less presence of comorbidity) in research clinics. Thus, two possibilities for improvement in interventions in clinical settings might be to employ more behavioral techniques, and to specialize clinics so that treatment can focus on circumscribed problems. Research clinics must also progress towards developing interventions that lend themselves better to real-world clinical practice. This may include developing interventions capable of addressing multiple problems sequentially or simultaneously.

5.06.5 PROCEDURES AND PROPOSED MECHANISMS OF CHANGE

Cognitive-behavioral therapy is an active, structured approach to treatment that aims to produce change in an individual's dysfunctional cognition and maladaptive behavior. Its procedures are based on the assumption that cognitive variables are important causal and maintaining mechanisms in the onset and course of a disorder, but that affective and behavioral variables are interrelated and influential as well. Specifically, CBT has been defined as those sets of therapeutic procedures that: (i) place primary importance on the causal/maintaining role of cognitive processes; (ii) use at least some therapeutic procedures aimed at altering aspects of cognition; (iii) examine cognitive, behavioral, and affective variables maintaining the disorder; (iv) may use both behavioral and cognitive techniques to target cognitive objectives, (v) emphasize empirical verification in research, assessment, and treatment; (vi) tend to be time-limited with the possibility of maintenance sessions; (vii) promote a collaborative relationship between client and therapist; and (viii) recommend active therapist participation during sessions (Ingram, et al., 1991).

Given this framework, one therapeutic pathway lies in remedying the identified dysfunction, focusing on the provision of skills and opportunities to practice these skills, and beginning new learning trajectories. One strategy for reaching this goal is the "consultative" role (also called "collaborative empiricism"; Hollon & Beck, 1979), in which the client and therapist work together as active collaborators in the identification of problems, the design and execution of tests of specific hypotheses, and the reanalysis of beliefs (Kendall, Vitousek, & Kane, 1991). As therapy progresses, the client learns to become an active and skeptical social scientist who has the ability to evaluate critically their own ideas, beliefs, and resulting behavior. Cognitive-behavioral theorists believe that data generated by the client in unbiased experiments, more than a therapist's credibility, persuasiveness, or authenticity, are the instigators of change. Treatment emphasizes inductive strategies for the modification of beliefs, operating from the assumption that "an actual demonstration of a belief's invalidity will go further to change a belief than will a discussion with the therapist" (Piasecki & Hollon, 1987, p.123).

A second therapeutic pathway lies in changing the valence of the child's self-talk. In one study of the treatment of youth with anxiety disorders (Treadwell & Kendall, 1996), negative self-talk was found to play a role in both predicting anxiety, and mediating treatment gains. It was hypothesized that negative self-talk, as opposed to positive self-talk, is predictive of maladjustment (Kendall, 1985). The results (Treadwell & Kendall, 1996) indicated that higher functioning was linked to fewer negative self-statements, but not to greater positive self-talk. Moreover, as children reduced their anxious distress, the accompanying negative self-talk became less frequent. The reduction of negative self-talk was found to mediate gains from CBT.

Procedures used by many CBTs include: affective education, relaxation training, social problem-solving, cognitive restructuring/attribution retraining, contingent reinforcement, modeling, role plays, and training workbooks. The behavioral component of CBT (e.g., modeling, role plays) is designed to illustrate the connection between mood and behavior and to provide practice opportunities for new skill-building. The cognitive component (e.g., cognitive restructuring, problem solving) is designed to teach the child to identify, re-evaluate, and replace maladaptive thoughts. Some techniques necessarily draw from both behavioral and cognitive concepts emphasizing the connection between thought, affect, and action.

Affective education teaches the child to recognize, label, and self-monitor physiological and emotional cues and, eventually, control behavioral reactions that accompany these cues. It focuses on gaining a greater understanding of one's outward manifestations of emotions to become aware of the situations that pose particular difficulties. Relaxation training, which is often tied to affective education, may be considered a first line of defense for children against increased levels of arousal. An objective in relaxation training is to teach the child to manage the physiological responses to emotionally stressful situations. The tandem of affective education and relaxation training free the child from the initial distress of a stressful situation and allow them to process information in a more reasoned and less dysfunctional manner.

Cognitive restructuring consists of strategies aimed at altering cognitive distortions or teaching skills to overcome cognitive deficiencies. The child practices identifying and testing the legitimacy of their own self-talk, or automatic thoughts, and changing self-talk to see the behavioral consequences. Attribution retraining is similar in that it teaches the child to be aware of the nature of their explanations for positive and negative outcomes. Reward and reinforcement can be used as either a method of motivating behavioral activity and teaching cognitive flexibility (as in children with internalizing disorders) or as a way of suppressing behavioral activity (as in children with externalizing disorders).

Modeling and role-playing are two techniques in which a therapist demonstrates to a child how to analyze and evaluate affect, cognition, and behavior. In coping modeling, the therapist describes a situation and relates how they might react in such a situation. The therapist would verbally proceed through the steps of identifying the problem, gathering and isolating key pieces of information, devising alternative actions, and thinking through and acting out conclusions. By modeling the entire scenario, the therapist illustrates to the child that effective problem solving involves a step-by-step process. Role plays enable the child and therapist to learn to be prepared for problems before they arise, and provide practice in the skills learned in sessions before attempting them in real-life situations.

Generally, CBT protocols have two portions. The first portion of the treatment plan focuses on educating the child in the above skills so that the child will be prepared ahead of time when difficult or challenging situations arise. The second half of the treatment plan generally is used to provide the child with opportunities to practice the skills which he or she has just learned. This is accomplished by having the clinician set up a number of manageable scenarios in the real world and allowing the child to confront the ensuing problems on their own.

Not all of the strategies are used identically in every case. Rather, the therapist uses judgment in adjusting strategies to be best suited to the child's developmental sophistication, presenting problem, and extra-therapy environment. Assuming that all children or all therapists are the same, or that all outcomes will be of a uniform type, would be to fall prey to the "uniformity myths" (Kiesler, 1966).

When designing a treatment strategy it is important that the plan includes training for generalization across skills and settings (Kendall, 1989). That is, the therapist must be mindful that mastery of a skill within the confines of the therapy room does not necessarily translate into successful application in the child's natural environment. A child who has demonstrated competence in giving a speech in front of a group may still have a fear of attending a party. To facilitate generalization, therapy can focus on "training diversely" (i.e., exposing the child to a variety of scenarios) so that the child will not be caught off-guard by novel situations (Stokes & Baer, 1977). The therapist can be mindful of current functional contingencies in the child's natural environment: for instance, if a child has difficulties asserting themself, the therapist, under the assumption that most teachers would provide positively reinforcing experiences, might set up an experience where the child must ask the teacher for help. The goal of generalization is to make the child aware that the skills learned in session are not unique to any individual setting, but useful across settings.

5.06.5.1 Proposed Mechanisms of Change

As mentioned previously, childhood disorders can be broken down into internalizing and externalizing varieties, each with cognitive dysfunctions (e.g., deficiencies, distortions). Children who exhibit externalizing behavior tend to display impulsivity and deficits in thinking whereas children with internalizing disorders tend to show overcontrol and distortions in thought. Because of these differences, it is reasonable that the strategies used in treatment accommodate to the specific cognitive needs of the child. Likewise, our notions regarding the active mechanisms involved in change reflect our conceptualization of the client within these categories.

Children with ADHD, for example, characteristically exhibit heightened motor activity, impulsivity, deficits in attention, and deficits in rule-governed behavior (Barkley, 1990). Treatment for children with ADHD tends to involve response-cost contingencies within a context of social reward to reduce unwanted behavior and increase the rates of desirable behavior. The primary goal of the CB therapist is to help the impulsive child internalize steps that can guide effective problem solving: identifying the problem, reflecting on solutions, making a decision, and taking action (Kendall, Kortlander, Chansky, & Brady, 1992). Therapy operates on the idea that the child is deficient in a particular cognitive skill (e.g., rule-governed and linguistically guided behavior) and that training can provide the necessary information to shape more positive behavioral trajectories.

On the other hand, modifying existing cognitive distortions is a primary component and proposed instigator of change in children with internalizing disorders, such as anxiety. Clinically anxious children may have excessive concerns about separation from their caregivers, as in separation anxiety, or they may excessively fear evaluation or rejection by their peers, as in social phobia. Such anxiety manifests in physiological (e.g., excess perspiration, or blushing), behavioral (e.g., avoidance, tremors), and cognitive (e.g., self-doubt, misperceptions of environmental demands) symptoms and can lead to severe interference in the child's daily activities. These distorted misperceptions of the demands in the environment, along with distorted underestimates of personal ability, exacerbate unwanted anxious arousal. The strategies used in treating anxious children may resemble those used with externalizing populations (e.g., social problem solving, modeling, positive reinforcement) but, with internalizing children, the process is focused on altering dysfunctional thinking (distortions) and changing related maladaptive behavior. Thus, the anxious child is taught to evaluate the legitimacy of anxiety-producing automatic thoughts ("If I go to the party, I'll just embarrass myself") and to reconsider less disturbing ways of looking at the world. The therapist helps the child develop a coping template that involves correcting misinterpretations, and viewing events and the environment through an alternative lens based on coping.

In aggression, both cognitive deficiencies and distortions may be present (Kendall, Ronan, & Epps, 1991). This combination requires multifaceted treatment. Also, with comorbidity being the rule rather than the exception, therapists must often combine strategies. In such cases, therapy has the dual function of filling in the gaps where information was needed and aiding the child in constructing a coping template which promotes alternative, healthy ways of thinking. Both components are viewed as essential if the child is to successfully overcome the challenges of adjustment.

In returning to the client as a social scientist, we can conceptualize CBT as any therapy which involves teaching the client strategies that will help them to: (i) formulate specific predictions relevant to their dysfunctional beliefs; (ii) design and carry out extratherapy experiments that bear on these predictions; and (iii) re-evaluate their original hypotheses with respect to the data that are obtained. This formulation might also include the act of supplying a client with any information that would facilitate the process of hypothesis testing (e.g. teaching the problem-solving steps to an impulsive child).

The reader is reminded that the CBT model does not propose to provide a cure for childhood disorders. Rather, it imparts, and promotes through practice, the ingredients essential for successful coping. The ultimate goal of CBT is not to eradicate the disorder, but to provide the child with multiple lines of defense so that they will have a sense of competence and control when confronted with stress and emotional arousal.

5.06.6 FUTURE DIRECTIONS FOR RESEARCH AND PRACTICE

With a rapidly growing proportion of researchers studying CBT (Kazdin et al., 1990; Klesges et al., 1982) and an expanding list of successful applications of CB to childhood disorders (see Kendall, 1993), there is reason to suggest that CBT will continue to undergo expansion. Attention to some key issues will assure the field's continued development. These issues include: (i) a growing need for development and study of standardized treatment manuals; (ii) an expanding emphasis on research aimed at understanding the active components of CBT, as well as understanding the underlying mechanisms maintaining childhood disorders; (iii) an increasing concern for the transportability of interventions from the research clinic to real-world service clinics; and (iv) a need for further study in the comparative and facilitative effects of pharmacological treatments.

Several randomized clinical trials evaluating CBT attest to its efficacy with some childhood disorders (e.g., anxiety, depression). More work needs to be done with disorders that have not been fully studied with CB protocols. The development and evaluation of manualized treatments, and the study of the role of flexibility in the use of manuals, deserves emphasis.

Demonstrating the efficacy of an intervention is a first step. Understanding the underlying behavioral and cognitive processes causing and maintaining a disorder as well as understanding the specific effects of therapeutic techniques is the second step. Which components are necessary? Which are helpful? Which are harmful? More clinical trials with active control groups (e.g., relationship therapy) may help examine the role of nonspecific factors of treatment. Such studies would allow us to begin to separate gains unique to the intervention from gains resulting from more general therapeutic factors.

Research is needed to determine the degree to which research clinic procedures can be transported to service clinics (Hoagwood et al., 1995; Kendall & Southam-Gerow, 1995). Are there client or therapist factors that contribute to differential outcomes? How are treatment-outcome studies received? Practicing clinicians may incorporate findings into their daily work, but research journals are not the practitioner's preferred method of receiving knowledge (Beutler, Williams, Wakefield, & Entwhistle, 1995). The transportability of research clinic interventions would benefit from progress on two fronts: first, research interventions should be tested in service clinics and any moderators of treatment should be examined; second, there needs to be more collaboration among research clinicians and service practitioners. Collaboration may help inform scientists on which areas of research are most relevant to practitioners and in what ways transportability could be improved. Such collaboration may help practitioners appreciate the value of data-supported interventions and inform practitioners how best to utilize findings from research clinics.

The recent pharmacological trend in treating mental health problems dictates that professionals within the field keep abreast regarding the usage and efficacy of pharmacological agents in treatment. Medications used in adult treatment are sometimes prescribed to children presenting similar symptoms but without the benefit of controlled, experimental evaluations. For example, in the treatment of depressed children and adolescents, various tricyclic antidepressants (TCA) (e.g., imipramine, desipramine, amitriptyline, and nortriptyline) and serotonin-specific reuptake inhibitors (SSRIs; e.g., fluoxetine, sertraline, paroxetine, and fluvoxamine) are commonly prescribed. However, despite what appears to be widespread general use of TCAs and SSRIs with children and adolescents, neither category of medication has consistently been demonstrated to be superior to a placebo (Jain et al., 1992; Simeon et al., 1990; Sommers-Flanagan & Sommers-Flanagan, 1996). Future research with pharmacological treatments with children needs to be directed toward determining the efficacy of the pharmacological agent alone or in combination with psychological interventions. Research addressing the comparative and facilitative effects of pharmacotherapy with youth is also required.

Much work remains in the application of CBT to childhood disorders. Applications of CBT for some disorders need to be developed, whereas in other disorders (e.g., anxiety, depression) research might focus on underlying cognitive processes and mechanisms of change. What aspects of cognitive processes and self-talk differentiate depressive from anxious self-talk? Which behaviors and cognitive processes show the greatest correlation with therapeutic change? Further research can also be done to enhance the transportability of CB interventions to practicing clinics. What are the factors that moderate outcome outside the research clinic's walls? What are the comparative and facilitative benefits of pharmacological treatments used in combination with CBT with children? Although CBT with youth is itself a relatively young approach, it has matured and continues to enjoy much activity and growth.

5.07.1 INTRODUCTION

Family systems therapy has emerged as a viable treatment for certain child and adolescent problems. In fact, for some clinical populations of youth, family systems therapy has been acknowledged as the "treatment of choice" (Gordon, Arbruthnot, Gustafson, & McGreen, 1988; Kazdin, 1993, 1994a; Liddle & Dakof, 1995a, 1995b). Despite its rapid growth in clinical and research settings, some continue to view family systems therapy as merely an adjunct to traditional individual modalities.

Family systems therapy, however, represents a "whole new way of conceptualizing human problems, of understanding behavior, the development of symptoms, and their resolution" (Sluzki, 1978, p. 366) in which the transformation of family interactions is its defining feature. Because interactions are viewed as pivotal in the etiology and maintenance of psychopathology, interactions are the ultimate target of intervention in family systems therapy.

Interactions are defined as the complex and interdependent patterns of behaviors and responses within the family. A fundamental assumption in family systems theory is that an individual's behavior is quite different from what it would be if it were possible for that individual to act in isolation. That is, the behaviors of individual family members are linked in an interdependent fashion, and each family member is viewed as being responsible for contributing to, maintaining, or changing the system's interactions (Szapocznik & Kurtines, 1989). The interdependent or linked behaviors among individuals tend to repeat, and ultimately become patterns of interaction that characterize the family system. It is these repetitive patterns of interaction that are the focus of family systems therapy.

While the family is at the core of the intervention strategy, family systems therapy appreciates the full range of systemic influences that affect the individual. For example, family systems therapy acknowledges the important influence of peers (Boivin & Begin, 1989; Dishion, French, & Patterson, 1995; Parker & Asher, 1987), school (Rutter, 1983), and the neighborhood (Brooks-Gunn, Duncan, Klebanov, & Sealand, 1993) on children and their families. A fuller appreciation of the range of systems that influence children and their families also includes biological processes (i.e., genetics) as well as individual psychological processes (i.e., cognitions). However, although the interface between the family and its context is acknowledged (Alexander, Barton, Waldron, & Mas, 1983; Szapocznik & Kurtines, 1993), it is the interactions that occur within the family that are the primary focus of intervention.

It is important to note that there is considerable heterogeneity within the field of family systems therapy in how different models of systemic intervention conceptualize and treat psychopathology. Some models focus relatively more on intrapersonal (i.e., psychodynamic, cognitive) processes, while others focus more on interpersonal (i.e., behavioral, multisystemic/contextual) processes. Such differential foci, however, tend to be a matter of emphasis rather than epistemology, and most models contain both intrapersonal as well as interpersonal elements. What cuts across family systems models, however, is a focus on patterns of interactions within the family. Thus, in this chapter, it is our intention to highlight the interactive and interdependent nature of family interactions that is ubiquitous to family systems intervention, rather than to draw attention to differences (often subtle) between the various systemic interventions.

In this chapter we present an overview of the development and current state of the science in family systems therapy with children and adolescents. By family systems therapy, we refer to clinical models that postulate underlying mechanisms which are based on the fundamental tenets of systems theory. To be included in this review, the intervention model had to contain a specific focus on processes (i.e., patterns of interaction) of the family system. By family, we refer to nuclear, blended, or other types of family arrangement. Intervention models more strongly rooted in behavioral theory are not reviewed in this chapter (for a review of these see Estrada & Pinsof, 1995).

5.07.2 THEORETICAL UNDERPINNINGS OF FAMILY SYSTEMS THERAPY

Considerable research indicates that social/contextual factors profoundly influence a child's developmental trajectory (Bronfenbrenner, 1995). Within the social context, the family has undoubtedly the most fundamental influence, having been referred to as the "bedrock" of child development (Bronfenbrenner, 1979; 1986; Szapocznik & Coatsworth, submitted for publication). The family system serves a critically important socialization influence for children and adolescents (Rutter & Cox, 1985); consequently, problems within the family system can dramatically influence youth. In fact, research has consistently demonstrated that problems within the family system are associated with a variety of psychological and behavioral problems in children and adolescents (Forehand, 1993; Kazdin & Kolko, 1986; Rutter & Garmezy, 1983).

So, what is the family system? How does it influence the child's development, including the development of psychological and behavioral problems? Is the family system amenable to change? And, if so, are these changes associated with improvements in the child's behavior? To answer these questions, it is important to understand some of the basic processes that underly the family system. In this section, some of the basic tenets of family systems theory are presented.

5.07.2.1 The Family System

The fundamental epistemology underlying family systems therapy is that of general systems theory (von Bertalanffy, 1968). In fact, the core assumption in family systems therapy is that the family operates according to basic rules and processes that govern all types of systems. From this perspective, a system is defined as a:

> circumscribed complex of relatively bounded phenomena, which, within these bounds, retains a relatively stationary pattern of structure in space or of sequential configuration in time in spite of a high degree of variability in the details of distribution and interrelations among its constituent units of lower order. (The system) responds to alterations of the environment by an adaptive redirection of its component processes in such a manner as to counter the external change in the direction of optimum preservation of its systemic integrity. (Weiss, 1969, pp. 11–12)

Chaos theory (Briggs & Peat, 1989; Gleik, 1987) can be used to explain the apparent paradox that a high degree of variability in the details of the behaviors of individual family members, in the context of the family, emerge as relatively stationary patterns of interaction over time and space. At the core of family systems theory is the notion that the family is a dynamic, self-regulating system comprised of interdependent parts that interact with one another in a somewhat predictable manner. The family system is dynamic in that it is comprised of individuals that interact and mutually influence one another (and their environment) continuously. And, it is self-regulating in that these interactions strive to maintain the integrity of the system. Integrity or self-preservation, however, are not equivalent to adaptive functioning. By maintaining integrity, we refer to the system's ability to maintain its characteristic organization regardless of whether this organization is adaptive or maladaptive.

The most important systemic principle that dominates family systems theory is that of interdependence. Interdependence refers to the complex connections and mutual influence of individual parts within a system. In families, interactions between and among family members are the primary means through which interdependence is defined. Understanding interactions—and consequently, interdependence—requires an understanding of the basic principles of systems theory. The following section briefly reviews some of the systemic principles that are critically relevant for assessment and intervention in the family context. This review is not exhaustive. For a more thorough review of systems principles see Broderick (1993), Buckley (1968), Goldenberg and Goldenberg (1996), Hanson (1995) and Steinglass (1987).

5.07.2.1.1 Wholeness: the whole is more than the sum of its parts

Basic to family systems theory is the assumption that the family is a dynamic system that can only be understood by overtly recognizing the complex interplay among all of its constituent parts. One cannot break the system down to its molecular parts, and then put the parts back together again to understand how the family operates. That is, achieving some level of understanding about an individual's internal (e.g., psychological) dynamics or a single aspect of family functioning (e.g., marital conflict) is useful, but it does not necessarily help the therapist predict (or even understand) how the family comes together and interacts as a system. It is only by examining the unique way in which the parts interact and reciprocally influence each other that the family system can be understood. This philosophy is represented in the systemic assumption that "the whole is more than the sum of its parts."

This is not to say that the individual parts of the family system are not important. In fact, we support attempts at formally integrating intrapersonal factors into family systems treatment (Breunlin, Schwartz, & Kune-Karrer, 1992; Liddle, 1994), and believe that future family systems model building must continue to build on such attempts to take into account the individual characteristics of family members. What we are trying to convey here, however, is that molecular examinations of the family do not capture the true complexity of the family system. And that even though "there is no phenomenon in a living system that is not molecular ... there is none that is only molecular, either" (Weiss, 1969, pp. 10–11). In other words, it is useful to understand how an individual family member interprets/processes information and how this processing influences their behavior; however, to understand the mutual influence and interdependent nature of family interactions such information must then be incorporated at the level of the family. Thoughts, feelings, and individual behaviors are thus considered to contribute to the interpersonal context of the family, but are not considered to be the defining features of the family. In family systems therapy, assessment and intervention occurs at both the molecular and molar levels. The therapist attends to the internal realities of individual family members and specific aspects of family relations (e.g., marital conflict), but also examines the unique way in which these aspects come together and influence the adaptive and maladaptive behaviors of the youth.

The essence of the concept of wholeness exists in the reality that although the family is comprised of multiple individuals with different emotions, beliefs, and behavioral repertoires, the family system develops its own unique identity that is not fully explained by these individual characteristics. As suggested in the biological sciences, the patterned processes that occur within systems do not occur because of some "prearranged, absolutely stereotyped mosaic of singletracked component performances" (Weiss, 1969, p. 9). Rather, these repetitive processes occur as individual parts in the system submit to the organizing rules of the system. In the family system, for example, although individual family members are capable of exhibiting an infinite number of interactions, they tend to interact in a manner that "fits" or is "consistent with" the governing rules of the family system.

The concept of "wholeness" has critical implications for treatment. For example, while individual family members' values, beliefs, and emotions, as well as particular relationships within the family (e.g., sibling, parent, parent–child) are considered to be important, systemic treatment must involve assessment and intervention at the level of the family as a whole. The family therapist is thus interested in changing the family's unique pattern of interaction. For example, an intervention designed to promote healthy connectedness between a parent and an adolescent must also take into account the impact that such an increase in connectedness will have on other aspects of the parent–adolescent relationship as well as on other individuals in the family. As is evident in this example, family systems therapists often target individuals or specific relationships within the family, but they do so with an explicit understanding of the potential reverberations that such interventions will have throughout the family system. It should also be noted that these interventions are typically utilized as a means to an end, and are often implemented as one aspect of a larger treatment plan that addresses changes in complex patterns of interaction at the level of the family system. Thus, in the scenario presented above, improving parent–adolescent connectedness may serve as a springboard for improving the parents' monitoring of the adolescent's behaviors. Moreover, this improved parent–adolescent bond may result in the formation of a new leadership subsystem (comprised of parent and adolescent) in which the adolescent is supported in taking over some of the developmentally appropriate leadership responsibilities within the family.

It is important to note that the concept of wholeness explains current family interactions, but does not explain why the family adopts one particular pattern of interaction over another. In fact, most family systems theories focus more on present interactions than on their historical antecedents. Many factors are likely to contribute to the emergence of specific patterns of interaction within the family, including individuals' predispositions (e.g., biological, personality) and personal history (e.g., family of origin, interpersonal relationships) as well as major developmental milestones (e.g., marriage, birth of children) and contextual factors (e.g., deteriorating conditions in neighborhoods, parent's loss of job).

When individuals first come together to form a relationship, their unique individual qualities probably define the possible range of interactions that may occur. Although there are an infinite number of possibilities that may occur within this range, specific patterns emerge and become relatively stable. As noted, the emergence of one pattern over another is probably influenced by many factors. While the relationship is partly determined by the persons involved, it cannot be predicted from the individual predispositions of each of its participants. The individuals involved in the interaction define the range of possibilities that may occur, but the specific pattern that emerges cannot be predicted from knowledge of each individual's potential.

Initially specific patterns may become repeated because they are personally gratifying to one or both of the participants or because it serves an important function in the relationship. As a particular interaction is repeated, it becomes increasingly stable and predictable, and, over time, may persist even if it no longer serves the important function it once served.

5.07.2.1.2 Boundaries: individuals, subsystems, and the environment

The systemic concept of "boundary" is a prominent aspect of family systems therapy. Conventionally, boundaries have been seen as the metaphorical "walls" that separate people, denoting where one person or group of persons ends and where the next begins. However, family systems theorists (Szapocznik & Coatsworth, submitted for publication) have recognized that just as boundaries signify separateness, they also denote connectedness. For example, the parent–child boundary not only signifies the distinction between the parenting subsystem and the child subsystem, but it also signifies the precise point at which they come together to interact as parent and child. Take for example an analogy from biology. Initially a cell membrane was viewed as a "wall" that helped contain the contents of the cell, and that separated the inside of the cell from the outside of the cell. This view provided the membrane with a certain "concreteness." A more contemporary view of a cell membrane, however, reveals that the "wall" is constantly negotiating transfer of biological components from inside to outside and vice versa. Thus, the cell membrane represents the cell's systematic mechanism for regulating transactions with its environment. This dynamic view of "boundaries" is reflected in the family systemic focus on the reciprocal process of interactions within the family, and between the family and its environment (Bronfenbrenner, 1979, 1986; Magnusson, 1995; Szapocznik & Coatsworth, submitted for publication). In families, boundaries are established by rules, both those that are discussed as well as those that are never discussed, but which everyone understands. Four important boundaries in family systems therapy are presented below.

The *family–environment boundary* denotes the separation/connectedness between the family and the environment. The simplest way of differentiating (or defining the family–environment boundary) a family from the environment is by examining biological relationships, or by examining who lives together and shares daily household responsibilities (Greenwood, Hervis, Mitrani, Taylor, & Szapocznik, 1995). Beyond these important distinguishing qualities, the family system is also characterized by its relatively stationary and unique pattern of interactions.

The boundary between the family and the environment is more or less permeable. That is, much like the membrane of a cell, this boundary regulates communication between the family and environment, and represents the precise point at which they intersect and reciprocally influence each other. (Note: Although we do not focus on it in this section, information also flows to and from the environment to specific individuals within the family. That is, individuals within the family also interact directly with the environment.)

The family–environment boundary may be critically related to the family's functioning, and is frequently an indication of potential problems in the family's ability to function adaptively. For example, Alexander (1988) notes that in families in which there is incest, the boundary between the family and environment is often rigid, resulting in increased insularity of the family, and an inability of the family to receive and respond adaptively to "feedback" from the environment.

The internal *family subsystem boundary* separates/connects subsystems within the family. The family system divides itself into various alliances to distribute its many roles and functions. These alliances are referred to as subsystems. Subsystems are typically organized by age or function. For example, the parental subsystem consists of the parents or, in single-parent families, the parent and another adult figure or an older child. The child subsystem consists of the siblings in the family (typically grouped together by age or gender). Subsystems are often utilized as the vehicle for completing the various roles and functions of the family.

The most important subsystem boundary in family systems therapy is the parent–child subsystem boundary. This boundary regulates the extent to which parents (or a parent and an older child, extended family member, or other parental adult) are able to work together as a unit to carry out the family's rules and responsibilities. Implementing rules, however, is only one way in which the parental subsystem interacts with the child subsystem. The parental subsystem is also responsible for caring, nurturing, and providing guidance to the youth. It should also be noted that influences at the parental subsystem and child subystem are bidirectional. The child subsystem also influences the parents. Take the case of a behavior problem youth as an example. The behaviors of these youths are frequently very intense and disruptive, and often elicit controlling responses by the parent(s). In fact, over time parents of behavior problem youth are likely to utilize many different strategies to attempt to manage or cope with their child's disruptive behaviors. This bidirectional influence is not limited to maladaptive interactions; in fact, in every family (beginning with the birth of children), children and parents continuously influence the behaviors of one another.

The *interpersonal boundary* separates/connects individual family members. This boundary represents the amount of separation/connection in each of the dyadic relationships in the family. At one extreme, this interpersonal boundary can be extremely rigid or impermeable (e.g., nothing gets through the boundary). When boundaries are so impermeable, the emotional and psychological distance between people is great. One strength in relationships in which there is an impermeable boundary is that individuals are often very autonomous and independent. However, a weakness in these relationships is that individuals do not benefit from supportive relationships, and they are more likely to experience existential crises and feelings of loneliness.

At the other extreme, the boundary can be far too tenuous. When boundaries are so tenuous, the emotional and psychological closeness between people is great. Individuals in relationships with highly permeable boundaries benefit from the supportive ties they have with other individuals. It is not uncommon for individuals in these relationships, however, to have difficulty establishing their own unique identity separate from other family members.

It is important to note that for any individual, the boundary separating/connecting them to other family members is unique to each particular relationship. For example, a father and his daughter may have a relatively permeable boundary in which there is a consistent, unobstructed flow of information. However, in the same family, there may be a rigid boundary between father and son in which communication is virtually nonexistent. Thus, the interpersonal boundary between individual family members is uniquely defined for each relationship in the family. In this sense, boundaries are considered to be characteristics of relationships rather than trait-like characteristics of individuals. (It should be noted that the interpersonal boundary is not unique to family relationships. Any relationship involves the continuous flow of information between its participants.)

The *interpersonal–intrapersonal boundary* represents the point at which interactions influence an individual's internal (i.e., psychological) world, and the point at which these internal processes influence the interaction. In family systems theory, the boundary between family interactions (interpersonal) and intrapersonal functioning is emphasized because of the family's profound influence on an individual's emotional and behavioral adjustment. All interpersonal relationships include emotional and cognitive intrapersonal components. These intrapersonal components influence the interpretation of information as well as the individual's behavioral response. Thus, the interpersonal–intrapersonal boundary regulates the flow of information from interactions with family members into the intrapersonal realm of the individual, where it is processed, and then ultimately influences the behavioral reactions of individual family members involved in the interaction.

5.07.2.1.3 Homeostasis, feedback, and change

As mentioned above, every system has built in mechanisms for ensuring its survival. The struggle for the survival of the system involves balancing between maintaining stability within the system and adapting to meet changing internal and external demands. Thus, there are two ways a system can function to maintain its viability. The first involves the process by which the system continuously monitors the activities of the family, and provides corrective feedback (information flow) to family members when they behave in ways that are not consistent with the family's rules. Such feedback operates to restore the family's equilibrium. This process, homeostasis, is critical for maintaining consistency and stability within the family over time.

However, because families are always in flux (e.g., children and parents' development, changing environmental conditions), there must also be mechanisms for ensuring that the family system adjust to meet the changing needs of its members or its environmental context. Similar to the processes involved in maintaining homeostasis, the process of change requires continuous feedback about the consequences of interactions within and outside of the family. As information is fed back to the system, the family is able to change those interactions that may have become obsolete or are leading towards the dissolution of the family. This process of the family system changing to meet changing internal or external demands is called recalibration.

A common example of how the recalibration process works and how it often goes awry in families is evident in the changing demands that are encountered as children mature during adolescence. The "task oriented" leadership style that may have worked when children were young often does not work when issues of autonomy and independence surface during adolescence. Parents must adjust their parenting style to fit the needs of the developing adolescent. Many parents continue to be very authoritarian (Baumrind, 1991a, 1991b) despite the fact that it is not working and that their child now requires a more flexible, negotiating parental style.

As the above example suggests, flexibility is a critical component in the recalibration process. That is, families must have the flexibility to adapt to changing internal and external circumstances. Flexibility is a measure of the system's ability to change and reorganize to meet changing needs. Flexibility also refers to the system's ability to adjust to the various situations confronting its members on a daily basis. To the extent that the system rigidly adheres to one pattern of interaction, the more likely it is that problems will arise. Thus, in a sense, flexibility refers to the inherent capabilities of the system and its ability to adaptively utilize a repertoire of interactions. More flexible systems are able to engage in a broader range of behaviors and are able to alter their patterns of interaction to meet the unique challenges they face on a continuous basis. Adaptive family functioning requires a balance between homeostasis and flexibility. Too much emphasis on stability prevents necessary adaptability, but excessive flexibility leads to chaotic family functioning (Minuchin & Fishman, 1981).

5.07.2.1.4 Complementarity

Family systems theory suggests that behaviors in an interaction are complementary (Minuchin & Fishman, 1981; Szapocznik & Kurtines, 1989), like a hand and glove are complementary: they fit together perfectly well. Thus, in addition to being inextricably linked to one another, family members' behaviors occur together as perfect counterparts. The basic assumption is that family members' behaviors mutually influence one another; consequently, any symptomatic behavior must be connected to other behaviors within the family. The principle of complementarity flows logically from the concept of interdependence (i.e., the connectedness and mutual influence of persons within the system). Thus, if a youth is using drugs, the question becomes: What are the complementary behaviors; that is, the behaviors that allow or encourage the youth to behave in this way? In other words, what are the social interconnections between family members that are conducive to drug use?

In addition to the complementary relationships among family members, family systems therapists are also concerned with the complementary interactions at the interface ("boundary") between the family and its social environment. For example, Steinberg and colleagues have shown that an authoritative parenting style is more strongly associated with academic achievement than nonauthoritative parenting style (Steinberg, Mounts, Lamborn, & Dornbush, 1991; Steinberg, Darling, Fletcher, Brown, & Dornbush, 1995). Thus, authoritative parenting behaviors are associated with/complement the child's academic achievement. However, this relationship appears to be moderated by ethnicity and peer group membership. European and Hispanic-American adolescents benefit more from authoritative parenting than African- or Asian-American adolescents (Steinberg et al., 1991; see also Florsheim, Tolan, & Gorman-Smith, in press). In part, this appears to be due to the nature of the peer groups with whom they affiliate. While in general adolescents from authoritative homes tend to associate with competent peers, for some ethnic groups it appears that the choice of which peer group one can associate with is restricted due to the neighborhood in which the child lives. Steinberg, Dornbush, and Brown (1992) found that Asian-Americans tended to associate with peers who support academic achievement, while the opposite was true for African-American adolescents in inner city neighborhoods. What these results suggest is that the nature of the peer group constrains the relationship between parenting style and academic achievement. It is also possible that parents may have an impact on the peer group. Thus, to fully understand the cross domain complementary (parent–peer) links associated with problem behaviors it is essential to consider the full range of intrafamily, adolescent–peer, and family–peer interactions that directly and indirectly influence the child's behaviors.

5.07.2.1.5 Reciprocal vs. linear causality

Family systems theory assumes reciprocal as opposed to linear causal explanations. Linear causality is based on the traditional stimulus–response behavioral view that one event "A" causes some response "B." This type of reductionistic thinking fails to capture the interdependence of individuals in any system. While it may be appropriate to highlight microanalytic sequences within the family (e.g., parents allow their adolescent daughter to stay out after curfew to avoid a confrontation with her), limiting our focus on these sequences fails to capture the true complexity of family interactions.

Circular causality assumes that any behavior in an interaction is simultaneously influenced by and influential on other behaviors in the interaction. In other words, causality is bidirectional. Thus, in the example of parents allowing their daughter to stay out after curfew to avoid a confrontation, a circular view of this sequence would begin with a recognition that the parent's behavior (e.g., avoiding confrontation) not only influenced the daughter's immediate likelihood of not being angry, but it also influenced the probability of her staying out beyond curfew in the future. Such a parental response may be the result of previous interactions in which the daughter responded with intense anger to the parent's confrontation. As a result, the parents' avoidance of confrontation in the current interaction may also influence the likelihood that the daughter will respond with intense anger to future parental confrontations of the daughter's behavior.

As is evident from this description, circular causality is informed by combinations of sequences of behavior. In this example only one particular sequence was highlighted. From a systemic perspective, however, it is not possible to understand a sequence outside of the context in which it occurs. Thus, to fully understand the mutual influence of parents and the adolescent in this example, the family systems therapist must also address other factors within the family (i.e., the parent's may not agree on basic rules within the house; consequently, they are unable to present a unified front to their daughter) or outside the family (i.e., the daughter may be associating with friends that foster an attitude of parental disrespect).

5.07.2.1.6 Process vs. content

Process can refer to the behaviors which are involved in an interaction; what and how things happen; as well as to the messages which are communicated by the nature of interactions or by the style of communication, including all that is communicated nonverbally such as feelings, tone, and power.

Content refers to the specific and concrete facts used in the communication. Content includes such things as the reasons that family members offer for a given interaction. For example, when a depressed mother says that her child is an obstacle to her completing school, it is important to attend both to the content (the specific issue raised) as well as to the process (the child being identified as the sole source of all of the family's problems).

Process and content may sometimes be contradictory. For example, an adolescent might say "I want help for my depression," while her behavior is that she disappears from home at the time agreed for family therapy sessions.

An emphasis on process (as opposed to content) is a predominate theme across family systems therapy models. The emphasis is on identifying the nature of the interactions in the family (diagnosis) and in changing those interactions that are maladaptive. Content is not ignored, particularly content that is emotionally valenced. However, the focus of therapy is on changing patterns of interaction. The therapist who responds primarily to content and loses sight of the process, will be unable to implement the kinds of family changes required to alleviate the problems experienced by the child.

5.07.3 HISTORY OF FAMILY SYSTEMS THERAPY

Most reviews cite the period directly following World War II as the most influential time in the evolution of family systems therapy (Goldenberg & Goldenberg, 1983). A variety of factors, including difficulties in the reunification process, the "baby boom," and changing social mores about familial roles and responsibilities created a large need for the development of a new wave of intervention that directly addressed family factors (Goldenberg & Goldenberg, 1983; Nichols & Schwartz, 1995). As a result of the large personal and societal demands, psychosocial interventions, including family therapy, flourished.

There are many excellent reviews that trace the development of family systems therapy, including landmark reviews by Guerin (1976), Goldenberg and Goldenberg (1983) Kaslow (1980), Nichols (1984), and Nichols and Schwartz (1995). Rather than summarize the work of these authors, this section focuses on those developments that directly contributed to our current conceptions of interactions, the cornerstone of the family systems approach. This review is not intended to be exhaustive. Our intention here is to chronicle the evolution of some of the critical events that led to our current conceptualization of the role of family interactions in the etiology and treatment of child and adolescent psychological problems.

5.07.3.1 The Family's Role in the Etiology of Schizophrenia

The 1950s was a critical decade in the development of the family systems approach. Four independent research groups proved to be the most influential in developing systemic theories of family functioning. Each of these groups were developing family theories about the development of schizophrenia.

5.07.3.1.1 Bateson and the Palo Alto Group

Bateson and his colleagues, the Palo Alto Group, were interested in developing a communication theory, which applies basic cybernetic principles within the family system, to explain the etiology of schizophrenia. The combined work of the Palo Alto Group provided the underpinnings for many of the current systemic theories of family functioning and family therapy. In particular, their systemic conceptualization of homoestasis, identified patienthood, and process vs. content is recognized in contemporary family systemic treatment models.

According to Bateson and colleagues (1972), whenever the integrity of the system is at stake, its natural tendency is to maintain homeostasis. One way in which the family system restores equilibrium is through a process in which one person becomes the symptom bearer. For example, an adolescent becomes severely depressed and suicidal whenever there is marital conflict, forcing the parents to stop fighting by refocusing on their child's depression. This process by which the child refocuses the problematic experience/event onto themselves labeled "identified patienthood," represented a shift in focus away from a purely intrapsychic conceptualization of the etiology of psychopathology towards a more interactional understanding of the onset of psychological problems.

Perhaps the greatest contribution of the Palo Alto Group to family systems theory was their conceptualization of the etiology of schizophrenia from a communication theory perspective. Bateson, Jackson, Haley, & Weakland (1956) introduced the concept of the double-bind communication as evidence of the family's role in the etiology of schizophrenia. It was their assumption that schizophrenia is caused by confusing communications within the family. In examining family conditions that precipitated schizophrenic episodes, they discovered that communication patterns in families with schizophrenic patients were characterized by confusion and contradiction. In particular, they noted that these communications occurred in the context of an important relationship, they contained two or more related but contradictory messages that also contained a threat (or perception of threat), and that the schizophrenic patient was forced to respond to these contradictory messages. For example, Bateson et al. (1956, p. 259) present the case of a young schizophrenic patient who was visited by his mother in the hospital. When she arrived, he put his arm around her and she stiffened. Sensing her discomfort he immediately withdrew his arm, and she responded by asking, "Don't you love me anymore?" The patient then blushed, prompting his mother to respond, "Dear, you must not be so easily embarrassed and afraid of your feelings." Following his mother's visit, the patient relapsed.

The concept of double-bind communications has influenced the development of several modern day family systemic concepts. For example, the concept of double-bind was the earliest articulation of the importance of process. Although content was critical in determining whether or not contradictory messages were in fact present, the primary emphasis was on the interactive process that was viewed as conducive to the development of schizophrenic symptomatology. For example, to engender schizophrenic behaviors, double-bind communications had to be a repetitive and stable characteristic of family interactions.

5.07.3.1.2 Lidz: the role of the marital relationship

Lidz may have been the first scientist interested in examining the role of the family in the etiology of schizophrenia. Lidz was strongly rooted in psychoanalytical therapy, and his primary interest was in understanding the way in which parents influenced the internal processes of identification and incorporation in their offspring (c.f. Nichols, 1984). However, through his intensive study of the families of schizophrenic patients, he developed a family theory of the origins of schizophrenia that brought together psychoanalytic theories about the important influence of parental personality on child development, and modern family systems theory.

In 1949, Lidz challenged Fromm-Reichmann's (1948) belief that a cold, domineering, and guilt-inducing mother ("schizophrenogenic mother") was responsible for the etiology of schizophrenia. In particular, Lidz documented the important contributions of fathers and—more importantly—the marital relationship, to the development of schizophrenia (Lidz & Lidz, 1949; Lidz, Cornelison, Fleck, & Terry, 1957; Lidz, Parker, & Cornelison, 1956). This transition from the individual to dyad to triadic relationships is a remarkable contribution to family systems theory.

Lidz is most recognized for his articulation of two types of marital relationships which contribute to the onset of schizophrenia. The first, "marital schism," involves a chronic failure in the marital relationship. In marital schism, spouses are in constant conflict and frequently undermine each other, openly competing for the loyalty of their children, and behaving in ways which fail to complement the behaviors of their partner. Quite often one partner, typically the father, is emotionally or physically disengaged from the family.

The second pattern, "marital skew," is characterized by severe psychopathology in one of the spouses. Spouses assume complementary roles which are pathological. One is dominant while the other is submissive. The dominant partner is typically the one with the serious psychopathology. Thus, even though on the surface they may appear strong and capable, their ability to provide direction and leadership within the family is severely compromised. The weaker partner goes along with and even supports the pathological tendencies of the superior parent.

Lidz et al., (1957) provided a complex rationale about the way in which "marital schism" and "marital skew" led to schizophrenia in girls and boys. What is important here, however, is his articulation of the relationship between family processes and the development of serious psychopathology. His observations and research went beyond the prominent linear cause–effect theories of the time, and prompted the development of a new wave of research and clinical development.

5.07.3.1.3 Wynne: the family unit

Wynne's theories of the role of the family in the development of schizophrenia profoundly influenced current family systemic theories' conceptualization of boundaries and alliances. According to Wynne (Wynne, Rycoff, Day, & Hirsch, 1958), interactions in families with schizophrenic members were characterized by two processes: pseudomutuality and pseudohostility.

Pseudomutuality is defined as interactions that give the impression that the family is functioning adaptively, but hide the fact that there are serious problems in the family. Boundaries in these families are very blurred, and individual autonomy and outside relationships are discouraged. He describes the boundary between the family and its environment as a "rubber fence" that stretches to allow some contact, but that is essentially impermeable. Thus, outside forces rarely precipitate a restructuring of family responsibilities; and, even if conflict between the family and its environment does emerge, the family responds by becoming even more insular.

Pseudohostility is similar to pseudomutuality, but involves a dramatic expression of conflict in response to minor disruptions in family alliances. Since the family is preoccupied with maintaining togetherness, a dramatic amplification of a minor problem actually operates as a "feedback" mechanism for the family. Family members move in quickly to repair the minor split and restore the system's togetherness.

Wynne's theories were critical in articulating the importance of boundaries and feedback mechanisms in the family system. His explanation of how a disturbance in family boundaries influences the development of major psychopathology represents one of the earliest structural interpretations of family functioning.

5.07.3.1.4 Bowen: multigenerational influences and the development of family systems therapy

Similar to Lidz, Bowen focused on disturbances in parental interactions, and their relationship to schizophrenia. In particular, Bowen (1960) coined the term "emotional divorce" to point out the emotional distance between the parents of schizophrenics. He claimed that children were often the only area in which these parents shared any common interest or were able to collaborate. Perhaps his most well-known contribution to the study of the family's role in the development of schizophrenia is his "three generation hypothesis."

According to Bowen (1960), the parents of schizophrenics are typically very disturbed individuals, who have themselves experienced serious problems with their parents which they are now replaying with their own children.

Bowen's work, however, goes well beyond his contributions regarding schizophrenic patients. In fact, Bowen is recognized as the father of family systems therapy (Papero, 1990). His theories influenced our current focus on triangulational, multigenerational interactions, and the sibling subsystem. He was also influential in adapting his family theories into a clinical model of family systems therapy. According to Bowen, family systems therapy is phasic, consisting of evaluation and intervention. To assist in the evaluative process, he developed the "genogram" as a method of depicting multigenerational patterns and influences (Papero, 1990).

5.07.3.1.5 About schizophrenia

Research of the family's role in the onset of schizophrenia was not merely coincidental. At this time, psychosocial interventions with schizophrenia were virtually ineffective and psychotropic medications were virtually nonexistent. The medical treatments that did exist (e.g., electroconvulsive therapy and lobotomy) were associated with severe side effects. There was obviously a strong demand for identifying causal pathways to the disease, and perhaps an even greater need for identifying effective interventions. Many of the assumptions of these early family theorists about the relationship between schizophrenia and pathological family relationships have since been refuted by contemporary theories and research of schizophrenia. Perhaps the error in these early theories about family process and schizophrenia was to not consider the possible impact of the child's schizophrenic functioning on parents' behaviors over the course of the child's development. Nevertheless, research with schizophrenia proved to be fertile ground for family therapy theorists to take their first steps.

5.07.3.2 Other Major Theoretical Figures in Family Systems Therapy

Among the most influential figures in the systemic movement were John Bell; Don Jackson—the founder of the Mental Research Institute—who was later joined by Virginia Satir, Jay Haley, John Weakland, Paul Watzlawick, Arthur Bordin, and Richard Fisch; Nathan Ackerman; Carl Whittaker; Ivan Boszormenyi-Nagy; Gerald Zuk; James Framo; Salvador Minuchin—the founder of the Philadelphia Child Guidance Clinic—who worked closely with Braulio Montalvo and Bernice Rosman; and Mara Selvini-Palazzoli at the Institute for Family Studies in Milan.

It is impossible to document all of the important contributions made by each of these leaders. Excellent reviews are found elsewhere (Guerin, 1976; Goldenberg & Goldenberg, 1983; Kaslow, 1980; Nichols, 1984; Nichols & Schwartz, 1995). Suffice it to say that nearly every current model of family therapy has strong theoretical ties to the work of one—and sometimes many—of these family theorists. These individuals were critical in bringing basic research and theory about family interactions to life in the clinical setting. They proliferated new theories about the family system and developed innovative techniques to modify family interactions. The seminal work of these investigators carried over into the 1970s as family therapists developed a new wave of techniques to change family interactions (Goldenberg & Goldenberg, 1983), including working with families at their home (Speck, 1964) and working in the community with extended family members, friends, neighbors and other persons (Speck & Attneave, 1973).

It is unfortunate, however, that the rush towards clinical practice was so profound that research into basic family processes and into the efficacy and effectiveness of family systems interventions was delegated to a lesser role. For example, in one comprehensive review of the literature Wells & Dezen (1978) identified only 20 well designed studies that examined the efficacy or effectiveness of family systems interventions. In the following section, we review evidence for the efficacy and effectiveness of family therapy models that have been influenced by the theoretical and clinical work of these early family systems theorists.

5.07.4 EFFICACY AND EFFECTIVENESS RESEARCH OF FAMILY SYSTEMS THERAPY

In reviewing the current empirical status of family systems therapy, our primary strategy involved identifying groups of studies or programs of research within a particular target population (e.g., depression, conduct disorder). Individual studies and case studies were excluded. The studies reported here are organized along three broad clinical domains: (i) mood disorders; (ii) psychosomatic disorders; and (iii) conduct disorders. Most of the studies cited here included randomization procedures for assigning cases to treatment, an appropriate comparison condition, and clear inclusion/exclusion criteria specifying a "clinical" child/adolescent population. Some of the effectiveness studies included in this review did not have a formal comparison group, but did have some degree of methodological rigor (e.g., pre–post assessments, procedures for monitoring of the delivery of intervention).

Although it was our intention to address the breadth of contexts in which family systems therapy has been applied, we attempted to identify those family models with rich empirical as well as clinical histories. It is our assertion that in a review chapter such as this it is important to include family interventions that have some level of empirical justification. We do not wish to downplay the potential utility of applying family systems therapy to a variety of clinical populations. However, we do wish to convey the importance of the interplay between theory, research, and clinical model building. Table 1 contains relevant information from selected studies in this review.

5.07.4.1 Mood Disorders

Similar to reviews by Kazdin (1994), Alexander, Holtzworth-Munroe, and Jameson (1994), and Estrada and Pinsof (1995), our review of the literature noted a lack of research on the efficacy and effectiveness of family systems therapy for internalizing disorders with children and adolescents. This section reviews the sparse research that does exist, and attempts to highlight promising programs underway at the time of writing.

5.07.4.1.1 Depression

We were not able to identify a single study that examined the efficacy of family systems therapy with depressed youth. In our discussions with family systems therapists and researchers, we were able to identify two significant depression studies. First, Brent and colleagues at Western Psychiatric Institute have made a large efficacy study (funded by the National Institutes of Mental Health) comparing the effects of different psychotherapy models, including family systems therapy, with depressed youth (Brent, personal communication February 8, 1997).

Second, Diamond (Philadelphia Child Guidance Center and Medical School of the University of Pennsylvania) and Siqueland (Medical School of the University of Pennsylvania) have adapted structural family therapy for treating depressed adolescents (Diamond & Siqueland, 1995). This approach integrates structural family therapy (Minuchin, 1974; Minuchin & Fishman, 1981; Stanton et al., 1982) and multidimensional family therapy principles (Liddle, 1991; Liddle, Dakof, & Diamond, 1991) as well as research on attachment. Therapy focuses on: (i) re-establishing or strengthening the parent–adolescent relationship to provide both structure and emotional support for the adolescent; (ii) decreasing marital or parent–adolescent conflict, and improving negotiation and communication within the family; and (iii) decreasing parental hostility and criticism. Diamond and Siqueland (1996) re port important changes in depressive symptoms, attachment, and family interaction in pilot cases. This model is under formal development (funded by the National Institute on Mental Health) at the Philadelphia Child Guidance Center.

5.07.4.1.2 Youth with Other Mood Related Symptoms

Henggeler and colleagues (in press) compared the effectiveness of multisystemic therapy (MST) to hospitalization for youth who presented with suicidal ideation, homicidal ideation, or threat of harm to self or others due to mental illness. MST (discussed further in Section 5.07.4.3.1), is a family-based, contextual approach that addresses the complexity of factors (family and environmental) that influence the youth's psychological and behavioral adjustment. In this pilot investigation, youth in multisystemic therapy showed a greater decrease in internalizing and externalizing symptoms than youth who had been hospitalized. MST was effective in reducing rates of hospitalization and total days hospitalized.

In a study conducted by Gutstein, Rudd, Graham, and Rayha (1988) a systemic crisis intervention was implemented with suicidal, depressed, or behavior problem youth who presented with an immediate crisis. The crisis intervention involved stabilizing family members' anxiety surrounding the crisis, mobilizing extended family members to become involved around the crisis, and restructuring family and extended family relationships to provide long-term solutions to the current crisis. Results demonstrate the effectiveness of the systemic crisis intervention in ameliorating family members' sense of crisis, limiting future suicidal attempts, and improving family functioning over time.

5.07.4.2 Psychosomatic Disorders

There are promising finding on the effectiveness of structural (e.g., Minuchin et al., 1975, 1978) and strategic (e.g., Palazzoli–Selvini,

Table 1 Review of selected publications.

Reference	*Model*	*Population*	*Design*	*Finding*
Mood disorders				
Diamond & Siqueland (1995)	Structural/ Multidimensional/ Attachment principles	Depression	Pilot data for 10 families participating in a treatment development study. Pre–post assessments of emotional problems, and intensive assessments of therapeutic processes included	Changes in depressive symptoms, attachment, and family interaction were noted
Henggeler et al. (in press)	Multisystemic (MST)	Suicidal or homicidal ideation, or psychosis	Participants ($n = 64$) were randomly assigned to MST or hospitalization, and completed assessments of emotional and behavioral problems at five time points. Monthly interviews monitoring utilization of mental health and juvenile justice services were also conducted	MST showed a greater decrease in internalizing and externalizing scores, and reduced rates of out-of-home placements and total days of stay
Gutstein et al. (1988)	Systemic crisis intervention (SCI)	Suicidal ideation or attempt, depression, violent behavior, or serious behavior problems	All participants ($n = 75$) received a brief systemic intervention ($<$ 20 hours), and completed four assessments of emotional and behavioral problems and family functioning	SCI effective in resolving crisis that precipitated treatment and decrease family dependence on institution
Psychosomatic disorders				
Minuchin et al. (1978)	Structural (SFT)	Anorexia	Participants ($n = 53$) were the first 53 anorectic patients treated. Data were gathered on the presenting characteristics of patients, the course of treatment, and follow-up data (approximately 2 years)	At follow-up, 86% of participants were rated as "recovered" from anorexia and its psychosocial components
Dare et al. (1990); Russell et al. (1987); Szmukler et al. (1985)	Structural/ strategic (SSFT)	Anorexia or bulimia	Participants ($n = 80$) were randomly assigned to SSFT or invidual therapy (IT), and completed assessments at intake and follow-up	SSFT and IT effective; however, SSFT was more effective when age of onset was before 18
Conduct disorder				
Alexander & Parsons (1973)	Functional (FFT)	Delinquent	Participants ($n = 86$) were randomly assigned to FFT, group therapy, psychodynamic family therapy, or control. Recidivism rates were obtained for 6–18 months following treatment	FFT more effective than other conditions in reducing recidivism rates

Table 1 continued

Reference	*Model*	*Population*	*Design*	*Finding*
Klein, Alexander, & Parsons (1977)	FFT	Siblings of youth in Alexander & Parsons (1973)	Arrests rates of the siblings of the delinquent youth in the original sample were compared at $2^1/_2$ year follow-up	Siblings of youth in FFT had lower rates of court involvement than siblings in other conditions
Barton et al. (1985)	FFT	Delinquent	Participants ($n = 74$) were referred to FFT or alternative treatment. Youth in the alternative treatment were selected to match youth in FFT. Number of arrests and recidivism rates were obtained for the 15 month period following incarceration	Youth in FFT were less likely to commit subsequent offenses than youth in alternative treatment. Youth in FFT also committed fewer offenses
Gordon et al. (1988); Gordon, Graves, & Arbuthnot (1995)	FFT	Delinquent	Participants ($n = 54$) received FFT or probation only. Recidivism rates were obtained for the 2–3 year period following intervention. In a follow-up study with these youth (now adults), court records from the next 3 years (5–6 years post intervention) were obtained	FFT reduced recidivism rates in the 2–3 year period following intervention (11% vs. 68%). Follow-up data show an arrest rate of 9% for FFT cases compared to 41% for the probation cases
Borduin et al. (1995)	Multisystemic (MST)	Delinquent	Participants ($n = 176$) were randomly assigned to MST or individual therapy. Assessments were administered at pre- and post-treatment	MST improved family functioning and adjustment, and prevented future arrests (4-year follow-up)
Henggeler, Melton, & Smith (1992)	MST	Delinquent	Participants ($n = 96$) were randomly assigned to MST or treatment as usual. Pre- and post-treatment assessments conducted, and criminal behavior and incarceration for 15 months following referral was obtained	MST reduced arrests and days incarcerated, and improved family functioning and peer relations
Henggeler et al. (1986)	MST	Delinquent	Participants ($n = 124$) received MST or treatment at a community agency. Participants were matched on important demographic characteristic. A nondeviant comparison group was included. Pre–post treatment assessments were completed	MST more effective in improving conduct, anxious-withdrawn behaviors, and family and peer relations
Szapocznik et al. (1989)	Structural (SFT)	Conduct disorder	Participants ($n = 69$) were randomly assigned to SFT, individual child dynamic psychotherapy (IT), or a no treatment control group. Assessments of behavior problems, family functioning, and individual dynamics were conducted at pre-, post-, and 1-year follow-up	SFT and IT reduced behavior problems. IT effective in improving individual dynamic functioning, but associated with a deterioration in family functioning, SFT effective in maintaining family functioning

Table 1 continued

Substance abuse				
Santisteban et al. (in preparation)	Structural (SFT)	Behavior problem (at risk) youth	Participants ($n=79$) were randomly assigned to SFT or a control condition administered in group format (CG). Assessments were conducted at pre-, post-, and at 1-year follow-up	SFT more effective than CG in improving behavior problems and in maintaining family functioning. Exploratory analyses suggest that improvements in family functioning may mediated treatment outcome in SFT; however, only in those cases identified as "poor family functioning" at intake
Szapocznik et al. (1983) Szapocznik, Kurtines et al. (1989)	One person family therapy (OPFT)	Behavior problem (at risk) youth	Participants ($n=75$; pooled sample) were randomly assigned to OPFT (individual sessions) or SFT (conjoint sessions). Assessments of behavior problems and family functioning were conducted at pre-, post- and follow-up	OPFT as effective as SFT in reducing behaviors problems and drug use, and in improving family functioning. Results demonstrate that a focus on family interactions in an individual treatment context yields results similar to those found in conjoint family sessions
Szapocznik et al. (1988)	Strategic structural systems engagement (SSSE)	Behavior problem (at risk) youth	Participants ($n=108$) were randomly assigned to SSSE or engagement as usual (EAU). EAU was designed to resemble community standards in engaging behavior problem youth in treatment. Treatment was monitored to ensure differential level of engagement interventions in the SSSE and EAU groups	SSSE was more effective than EAU in engaging families and youth into treatment. Participants in SSSE were also more likely to complete treatment than participants in EAU
Santisteban et al. (1996)	SSSE	Behavior problem (at risk) youth	Participants ($n=193$) were randomly assigned to engagement family therapy (SSSE + SFT), family therapy (SFT only), and group therapy (GT only). Treatment was monitored to ensure differential levels of engagement interventions across treatment groups	Results demonstrate the effectiveness of SSSE in engaging participants into treatment. Further analyses shed light on variables moderating the effectiveness of the specialized engagement interventions
Liddle et al. (1997)	MDFT	Substance abuse	Participants ($n=95$) were randomly assigned to MDFT, adolescent group therapy, and multifamily educational intervention. Assessments were conducted at intake, termination, and at 6 and 12 month follow-up	MDFT demonstrated lower drug use and higher grades at termination than the alternative treatments. Results were maintained at 12 month follow-up

Boscolo, Cecchin, & Prata, 1974) family systems therapy in the treatment of psychosomatic disorders (e.g., eating disorders, diabetes, asthma). Much of this work is represented in the widespread publication of numerous case studies demonstrating the positive effects of family therapy with psychosomatic youth. However, a solid empirical base for family systems therapy is also emerging.

Family systems intervention with psychosomatic youth is traced directly to the work of Minuchin and colleagues at the Philadelphia Child Guidance Center. In their initial work, Minuchin et al. (1978) described five characteristics of "psychosomatic families": (i) enmeshed subsystem boundaries; (ii) overprotectiveness; (iii) rigidity; (iv) lack of conflict resolution; and (v) the child's involvement in parental conflict. In an initial study of structural family therapy, Minuchin et al. reported an 86% recovery rate.

There is considerable controversy, however, about the notion of whether there is such an entity as the "psychosomatic family." Coyne and Anderson (1989) assert that over-protection and enmeshment may be adequate responses of a system to the crisis of the patients. Moreover, other researchers (Garfinke & Garner, 1982; Grigg & Friesen, 1989; Marcus & Wiener, 1989) have found no unique pattern of family interaction that characterizes these families. This controversy is further fueled by the fact that Minuchin's impressive findings have never been replicated in subsequent studies (Kog, Vandereycken, & Vertommen, 1989).

Nevertheless, family therapy appears to be beneficial for patients with eating disorders (e.g., Kog & Vandereycken, 1989). For example, in what is perhaps the best designed study in this area, Dare and his colleagues (Dare, Eisler, Russell, & Szmukler, 1990; Russell, Szmukler, Dare, & Eisler, 1987; Szmukler, Eisler, Russell, & Dare, 1985) compared the efficacy of structural/strategic family therapy and individual therapy with anorectic and bulimic patients. Results demonstrate that both family and individual therapy are effective treatments with anorexic and bulimic patients. However, certain pretreatment patient attributes interacted with treatment. For example, family therapy was more effective than individual therapy when the patient's age of onset for the eating disorder was below 18.

Taken together, these results suggest that family systems therapy may be a promising treatment for adolescents with eating disorders. Although there is considerable controversy about whether or not there is a distinct entity called the "psychosomatic family," the overall results of treatment research in this area are encouraging. However, further research is needed to investigate the assumed theoretical mechanisms of action: the potential mediating role that changes in family interaction may have on treatment outcome with psychosomatic youth.

5.07.4.3 Conduct Disorders

In contrast to research with internalizing disorders, there is a large body of treatment research on the efficacy and effectiveness of family systems therapy with conduct disorders. Reviews of the treatment outcome research literature have consistently documented the efficacy and effectiveness of family-based approaches with problem behavior youth (e.g., Alexander et al., 1994; Chamberlain & Rosicky, 1995; Gurman, Kniskern, & Pinsof, 1986; Kazdin, 1993, 1994; Liddle & Dakof, 1995a, 1995b; Nichols & Schwartz, 1995; Tolan, Cromwell, & Brasswell, 1986). In this section, we review family systems interventions for youth with delinquency and substance abuse.

5.07.4.3.1 Delinquency

Family systems therapy has received extensive support with delinquent and behavior problem adolescents. Two programs of research have emerged for working with these youth: Functional family therapy and multisystemic family therapy.

Alexander and colleagues at the University of Utah have developed, refined, and evaluated the effectiveness and efficacy of functional family therapy (FFT; Alexander & Parsons, 1982; Barton & Alexander, 1981) with delinquent youth. FFT is based upon early family systemic (e.g., Haley, 1976) and behavioral (e.g., Patterson, 1971) frameworks, and has clearly identified and manualized specific phases of treatment (Alexander & Parsons, 1982; Morris, Alexander, & Waldron, 1988). Each phase includes a specific description of goals, requisite therapist characteristics, and techniques (Alexander et al., 1983).

In the initial phase of treatment, the introduction phase, the focus is on therapist characteristics that enhance the family's expectations about therapy. Empathy, compassion, and professionalism are all critical features of this phase. The key feature of this phase is that the therapist attempts to maximize the likelihood that the family will return for additional sessions with "hope" that family therapy can be beneficial.

In the second phase of treatment, the assessment phase (described below, see Section 5.07.5.2.1), the main therapeutic task is to identify the interpersonal relatedness needs (i.e., functions) of family members, and the maladaptive interactions and behaviors that family members implement to meet these needs.

In the third phase of treatment, the therapy phase, the main goal of the therapist is to create a motivational context that is conducive for long-term changes to occur. As in the introduction phase, basic therapist relational skills are a requisite for this phase; however, to meet the goals of this phase, these skills include the extensive use of therapist reframing to disrupt negative, defensive family interactions.

In phase four, the behavior change phase, FFT prescribes a greater emphasis on therapist structuring characteristics. Although relational skills are still important, therapists utilize a battery of behavioral techniques to promote behavior change within the family (Alexander et al., 1983). Techniques fall into three major classes: communication training, assignment of specific activities, and use of technical aids. FFT further emphasizes that these specific techniques must be tailored to the unique characteristics of each family, and must be consistent with the capabilities and interpersonal relatedness needs of each family member (Alexander et al., 1994; Barton & Alexander, 1981). Resistance to behavior change is redefined as the failure of the therapist to adequately motivate family members to change, an inappropriate assessment of interpersonal needs (i.e., functions), or the implementation of behavior change techniques that are not consistent with the functional needs of individual family members. Hence, resistance is moved from an intrapersonal or intrafamilial to a therapeutic holon.

Finally, in phase five, the generalization phase, the therapist is focused on generalizing the gains made in therapy to real world settings. Problematic interactions in other systems are identified and targeted for change, and potential future problems are anticipated and strategies are generated to deal with these problems.

In their initial investigations (Alexander & Parsons, 1973; Parsons & Alexander, 1973), FFT was shown to be superior to client-centered group therapy, psychodynamic family therapy, placebo treatment condition, and no-treatment control groups in reducing recidivism with primarily "status" offending adolescents. In a two and a half year follow-up (Klein, Alexander, & Parsons, 1977), siblings of youth in the FFT condition had significantly lower rates of court involvement than siblings from youth in the other conditions. In a subsequent investigation, Barton et al. (1985) further demonstrated the effectiveness of FFT by extending these findings to multiply offending delinquents. Independent researchers have also documented the efficacy and effectiveness of FFT with behavior problem youth (Friedman, 1989; Gordon, Arbuthnot, Gustafson, & McGreen, 1988). In one investigation, examination of arrest rates during the three years following intervention, reveals that FFT cases (now adults) have an arrest rate of 9% for criminal offenses, compared to a 41% arrest rate for youth who had received probation services only (Gordon, Graves, & Arbuthnot, 1995).

Henggeler and colleagues' MST (Henggeler & Borduin, 1990) has also received extensive recognition for its effectiveness with delinquent youth. MST was developed for working with youth with severe delinquency and behavior problems. In MST, interactions in the family are critical; however, interactions with other important systems are also targeted. In particular, MST addresses interactions with school, peers, and juvenile justice. MST borrows from many models of family systems intervention to facilitate changes in the family system, and does not articulate a unique family systems component. MST has been shown to be effective in reducing delinquency, substance use, and other behavioral problems in several well-controlled randomized investigations (Borduin, Henggeler, Blaske, & Stein, 1990; Henggeler, Melton, & Smith, 1992; Henggeler et al., 1986). Perhaps more than any other family therapy model with adolescents, MST is having an impact at the policy level, as reflected by its adoption for public funding.

5.07.4.3.2 Substance abuse

Family systems therapy (FST) is also gaining recognition as an effective alternative for treating adolescent substance abuse. Liddle and Dakof (1995a, 1995b) note that a number of studies have been conducted since the mid-1980s examining the efficacy and effectiveness of FST with this clinical population (Azrin, Donohue, Besalel, Kogan, & Acierno, 1994; Friedman, 1989; Henggeler et al., 1991; Joanning, Thomas, Quinn, & Mullen, 1992; Lewis, Piercy, Sprenkle, & Trepper, 1990; Liddle & Dakof, 1994; Liddle et al., in press).

Liddle and Dakof (1995a, 1995b) also highlight Szapocznik and colleagues' program of research examining the efficacy of structural family therapy (SFT) with substance abusing youth (Szapocznik, Kurtines, Foote, Perez-Vidal, & Hervis, 1983, 1986; Szapocznik et al., 1988). This program of research has attempted to identify the needs of minority families and to develop, demonstrate, and investigate intervention strategies for substance abusing, behavior problem youth. The version of SFT that has emerged from this research

(Szapocznik & Kurtines, 1989) draws from structural (Minuchin, 1974; Minuchin & Fishman, 1981; Minuchin, Rosman, & Baker, 1978) and strategic (Haley 1976; Madanes, 1981) traditions in family therapy theory as well as from a rich clinical and research history working with inner city minority families.

Central to SFT theory is the concept that dysfunctional family structures (i.e., repetitive patterns of family interaction that characterize the interdependence of family members) give rise to or maintain the youth's problems (Minuchin Montalvo, Guerney, Rosman, & Schumer, 1967; Minuchin, 1974; Minuchin & Fishman, 1981; Szapocznik & Kurtines, 1989; Szapocznik & COSSMHO, 1994). Thus, the focus in SFT is on diagnosing and correcting repetitive patterns of interaction.

The three basic techniques in SFT are joining, diagnosing, and restructuring (Minuchin & Fishman, 1981; Szapocznik & Kurtines, 1989; Kurtines & Szapocznik, 1996). "Joining" refers to establishing a therapeutic relationship, in which the therapist is both a member and the leader, and that includes all family members. Joining, in addition to establishing rapport with each family member, requires identifying interactional patterns that guide family functioning; respecting such interactional patterns; and, entering the family by utilizing its established structure. As described in more detail below (see Section 5.07.5.2.2), diagnosis occurs along five dimensions: (i) structure, (ii) resonance, (iii) developmental stage, (iv) identified patienthood, and (v) conflict resolution.

"Restructuring" defines the broad range of interventions that the therapist undertakes to change maladaptive interactional patterns identified in the diagnostic process. These techniques represent a set of complementary tools that are not intended to be independent of each other, and include:

(i) *Working in the present*—the active ingredient is transforming family interactions in the here and now, which is distinguished from the typical use of "here and now" that refers to the intrapersonal process of experiencing feelings in the present. This present orientation is defined in terms of a focus on the process of family interactions, rather than on their content, or individual processes.

(ii) *Reframing*—represents a strategy of cognitive restructuring that promotes a new understanding or meaning for the family which in turn permits new and more adaptive interactions to emerge.

(iii) *Shifting boundaries and alliances*—involves breaking inappropriate alliances between family members and creating more adaptive and flexible alliances. For example, a common problem in families with a drug using adolescent is the tendency of parent figures to deflect dyadic conflict by involving the problem adolescent in the conflict. This process, labeled triangulation, often occurs when a lopsided alliance is formed between one parent figure and the problem youth against the other parent figure. By better balancing the overly strong and overly weak parent–youth alliances, and the overly weak parental alliance, more direct/uninterrupted communication between the parent figures gives rise to a new and stronger boundary around the parents.

(iv) *Redirecting communications*—involves promoting direct and specific communication between dyads, which sometimes requires blocking the interference of family members that do not permit such communications to occur.

In their initial investigations, Szapocznik and colleagues demonstrated that a family approach was effective with Hispanic families (Scopetta et al., 1977), and that family psychoeducational interventions rich with cultural content and aimed at transforming family interactional patterns could produce results as strong as family therapy (Szapocznik, Santisteban et al., 1986). In a subsequent study, combining a family approach with a cultural intervention, they demonstrated significant improvements in children's problem behaviors and family functioning (Szapocznik, Santisteban et al., 1989). In separate investigations, the efficacy of SFT with substance abusing and at risk adolescents was compared to a group therapy control condition (Santisteban et al., 1996, 1997) and individual dynamic psychotherapy (Szapocznik, Rio et al., 1989). In the former investigation, SFT produced significantly greater improvements in behavior problems than group counseling. Moreover, analyses of clinically significant change revealed that a substantially larger proportion of family therapy cases demonstrated reliable clinical improvement in behavior problems than did group cases. In the latter study, both SFT and the individual dynamic psychotherapy condition demonstrated significant improvements in behavioral problems (as compared to a no-treatment control group). However, SFT resulted in one-year follow-up improvements in family functioning, while individual dynamic psychotherapy resulted in a one-year follow-up deterioration in family functioning.

Szapocznik and colleagues have also developed and investigated two unique applications of SFT. The first application, one person family therapy (OPFT), is an intervention that is designed to target changes in maladaptive family interactions, but that attempts to do so without the whole family present in therapy (Szapocznik & Kurtines, 1989; Szapocznik, Kurtines, Perez-Vidal, Hervis, & Foote, 1989). OPFT has been shown to be as effective as the conjoint family approach in bringing about and maintaining significant improvements in: (i) behavior problems and drug use in youth, and (ii) family functioning (Szapocznik, et al, 1983; Szapocznik, Kurtines et al., 1986). For one-person interventions to produce desired changes in family interactions they had to explicitly target family change (Szapocznik, Rio et al., 1989).

The second application, strategic structural systems engagement (SSSE; Szapocznik & Kurtines, 1989; Szapocznik, Perez-Vidal, Hervis, Brickman, & Kurtines, 1989), was designed to more effectively engage adolescent drug users and their families in treatment. This approach was designed to overcome resistance by restructuring the interactions that permit resistance to occur. A core assumption in SSSE is that resistance is interaction-based; and consequently, therapists can strategically alter their behaviors to change the interactions that are interfering with the engagement process. In separate investigations with drug using Hispanic youth (Santisteban et al., 1996; Szapocznik et al., 1988), SSSE was significantly more effective than conventional engagement procedures in engaging in youth and their families into treatment. Moreover, the dropout rates in therapy were up to three times lower for families that had received the SSSE intervention than for those families that had not received this intervention.

Liddle and colleagues have developed and refined multidimensional family therapy (MDFT; Liddle; 1992, 1995) for inner city adolescent substance abusers. MDFT is an integrative family-based intervention that draws from structural family therapy, social learning theory, developmental theory, attachment theory, and empirical work (Liddle, 1994) to guide assessment and intervention within four interacting systems: (i) family system; (ii) parent–adolescent relations; (iii) parent subsystem—the self of the parent (parent as a parent and an individual adult); and (iv) adolescent subsystem—the self of the adolescent (adolescent as a son or daughter and as a member of a peer culture). Preliminary evidence for the efficacy of MDFT has been demonstrated in a controlled randomized clinical trial study comparing MDFT to adolescent group therapy and a multifamily educational intervention condition (Liddle et al., in press). Results demonstrated MDFT's superiority in reducing drug use and improving grades. The results from this study are currently in preparation. Data are currently being collected in a second National Institute on Drug Abuse funded controlled clinical trial study which compares MDFT to an individual-based cognitive therapy condition.

5.07.5 ASSESSMENT AND CLINICAL FORMULATION

The presenting problem or symptom exhibited by the child or adolescent (e.g., depression, substance abuse) is the family's ticket to coming to therapy. Family members typically enter therapy with the explicit goal of wanting to change the youth, and have minimal awareness of their own contribution to the problems experienced by the youth. For the family systems therapist, however, family interactions are the primary focus of treatment. The key to effective intervention thus begins with an accurate assessment and clinical formulation of family interactions that are related to the youth's problems. Assessment and clinical formulation (and ultimately intervention) always consider the general nature of family functioning as well as the specific relationship between the presenting problem and general family functioning.

Assessment and clinical formulation involves identifying strengths and weaknesses within the family. Weaknesses (i.e., problematic interactions) are presumed to be directly linked to the problem presented by the child. For example, parental conflict, parent–child relationship, triangulation, and a lack of subsystem differentiation, may all be related to the problem experienced by the child or adolescent. Family systems interventions reflect this focus on problematic interactions.

It is important to note, however, that the therapist's assessment of the family's strengths is perhaps as important as identifying weaknesses. Strengths refer to adaptive family interactions as well as to the particular capabilities of individual family members. This focus on strengths is not merely "lip service" or a reaction to "pathology-based" intervention models. Because the majority of family systems interventions are brief and problem-focused, therapists must utilize the family's resources to maximize their impact on the family. Although treatment does involve some skills building, it is not the primary focus of intervention. Rather, the primary focus is on utilizing the family's strengths to achieve the goals of treatment.

At a microlevel (moment by moment) in treatment, the therapist looks for intrapersonal and interpersonal strengths. Some examples of intrapersonal strengths include positive features such as love, commitment, and a desire to make things better. Interpersonal strengths include open and direct communication between family members, positive expressions of support, and the healthy expression of differences of opinion. These strengths are contrasted with microlevel intrapersonal and interpersonal weaknesses. Intrapersonal weaknesses at this level include hopelessness, anger (at worst, hate, or contempt), and negative attributions about self or other. Interpersonal weakness include the expression of contempt (as opposed to appropriate disagreements), intense and escalating levels of negativity, vague and indirect communication, developmentally inappropriate parent or child behavior, and conflict between parent figures.

At a molar level (assessment and clinical formulation of the family system), the strengths and weaknesses of complex patterns of interaction are considered. Some examples of strengths at this level include the family's flexibility to respond to changing internal (within family) and external conditions, their ability to negotiate and resolve their differences of opinion, and their ability to recognize that their problems are multifaceted as opposed to residing within one family member. Weaknesses at the molar level include a lack of parental cooperation in setting and enforcing rules, overly connected or disconnected interpersonal boundaries, the centralization of one family member, and the consistent denial, avoidance, or diffusion of family conflict.

5.07.5.1 Conducting Assessments in Family Systems Therapy

Family therapists are active and directive. They gather information about family interactions by asking directive questions about family interactions and by encouraging family members to interact in the treatment context. The process of assessment and clinical formulation, however, varies across family systems models. Thus, there is no standard, universally accepted procedure for conducting assessments and clinical formulation. Nevertheless, some of the strategies for assessing interactions are similar across models. In this section, we describe two general strategies for conducting assessments in family systems theory: (i) the family genogram, and (ii) enactments.

5.07.5.1.1 Family genogram

The genogram is a frequently used method for identifying who is in the family, and what role important family members play with respect to one another. The conventional genogram includes biological family; however, genograms may also include individuals based on the function they serve within the family. For example, in our own work with inner city African-American families (Greenwood, Herves et al., 1995; Greenwood, Samuels, et al., 1995), defining "family" solely through biological relationships fails to represent the complex family/kinship network of these families. What is required is a more flexible approach to identifying family/kin that examines: (i) blood relation and/or extended kinship; (ii) perceived strength and duration of relationships; and (iii) perceived support—in either direction—(including financial, emotional, and instrumental help, e.g., who provides transportation, child care, and other types of assistance). In our experience, "family" often includes all individuals living within a household (except for roommates and transient "live-ins") as well as other important significant others who may or may not be biologically related to one another.

The genogram is like a family tree in that it depicts all of the important relationships within the family. One of the most important reasons for constructing a genogram is to obtain a more complete picture of the family constellation. The genogram is a tool for systematically identifying who is in the family—getting around the common problem of some families not letting therapists know about key but conflicted or undesirable relations. Thus, the genogram can also be useful in helping the therapist depict adaptive and maladaptive family interactions (e.g., conflicted or supportive relations may be depicted using a jagged line or straight line).

There are many strategies for conducting genograms, and various symbols are used to denote meaningful relationships and/or roles within the family. Regardless of the strategy or symbols used, the genogram is an excellent method for organizing the complex interconnections between family members in a coherent, organized manner. The drawback of the genogram is that it is a "snapshot" of the family, and as such yields relatively little information about family interactions. In other words, the genogram tends to be static rather than dynamic. Genograms represent the first stage of the assessment process, and are often used to establish rapport and gather information about who are the potentially critical "players" in the youth's life. This information provides the context for further assessment into the dynamic interaction patterns that characterize the family members identified in the genogram.

5.07.5.1.2 Assessment through direct observation of family interactions: enactments

Minuchin and colleagues (Minuchin, 1974; Minuchin & Fishman, 1981) were the first to emphasize the importance of enactments in FST. In fact, they describe enactments as the primary vehicle through which interactions are identified and changed in therapy. Enactments are defined as family interactions in the treatment context that reflect the family's characteristic manner of interacting outside of therapy. That is, enactments reflect the family's overlearned behaviors that are present in most situations. Enactments allow the therapist to directly observe family interactions, and are thus critical for assessment and clinical formulation. The basic philosophy is that family members will enact "real world" interactions through their enactments in the treatment. Thus, by observing these enactments in therapy, the therapist can directly assess strengths and weaknesses within the family, including important changes in family interaction that occur as therapy progresses.

Enactments are promoted by a therapeutic focus of encouraging, helping, or allowing family members to behave/interact in their characteristic manner, that is, as they would naturally behave if the therapist were not present (Szapocznik & Kurtines, 1989). Very frequently family members will spontaneously enact in their typical way when they fight, interrupt, or criticize one another. However, because of the nature of therapy, it is not uncommon for family members to centralize therapists, in which case, the therapist will need to be more active in facilitating direct communication between family members (i.e., enactments). To facilitate enactments, the therapist systematically redirects communications to encourage interactions between family members.

Enactments permit the therapist to view the family directly as it really is, with its overlearned, rigidly repetitive patterns of interaction. In this case, the therapist observes problems directly and does not have to rely on stories about what typically happens when the therapist is not present. By doing so, the therapist gathers information about family functioning directly by facilitating family interactions in therapy. We believe that there can be considerable discrepancies between what individuals report and how they actually behave (enact) in the family context. Moreover, family reports tend to be influenced by attributions; whereas, observations of enactments permit the identification of circular/systemic processes.

5.07.5.2 The Underlying Nature of Family Interactions

In clinical work, there is a range of theory driven information that is obtained through assessment. In this section, we present assessment information from two theory driven interventions for which there is also considerable efficacy research.

5.07.5.2.1 Functional family therapy

In FFT, the therapist's assessment is designed to identify the "functions" of each family member in relation to one another. Functions represent a short-hand term for the relational needs, whether they be inborn or learned, that underly individuals' apparent motivations for distance/autonomy and connectedness/interdependency with others (Alexander & Parsons, 1982). These patterns become evident over time in relationships, and often differ for a given individual in different relationships. Thus, unlike the intrapersonal concept of "personality" which presumes a core underlying motivational structure, a functional family therapist's assessment of functions often identifies important motivational differences within one person. A parent, for example, may have a "favorite" child (with whom they might even be "enmeshed"), while at the same time have another child whom they reject and may even attempt to expel from the household. In such situations it is inappropriate to think of the parent in a unitary fashion (enmeshed or disengaged). Instead the functional family therapist understands that the motivational needs of the parent, and perhaps the children, with respect to each other are markedly different. As a result, behaviors that would be syntonic for the parent with respect to the "close" child could be quite dystonic with respect to the "distanced" child. Additional complexity occurs when the motivational structure differs for members of a dyad—for example, a parent retains strong affiliation (connectedness needs) towards a youth, while the youth is "emancipating" (distancing from the parent) and developing much stronger connectedness needs outside the family. In FFT, neither the parent's functional need with respect to the child or the child's functional need with respect to the parent are pathologized. Rather, the therapist identifies the maladaptive behaviors that a person is using to meet their functional needs. For example, adolescents who sneak out of the house after curfew to hang out with friends may be considered to have an interpersonal (i.e., functional) need for distance from their parents. However, the manner in which they are fulfilling this need is considered to be inappropriate (e.g., sneaking out of the house). In FFT, the goal of assessment and clinical formulation is to identify each family members' functional needs with respect to other family members, and to understand the adaptive and maladaptive behaviors that are being utilized by family members to maintain these interpersonal needs.

5.07.5.2.2 Structural family therapy

A different strategy for assessing family interactions is found in the work of Szapocznik and colleagues (Hervis, Szapocznik, Mitrani, Rio, & Kurtines, 1991; Szapocznik & Kurtines, 1989; Szapocznik et al., 1991). The core of assessment and diagnosis in SFT involves identifying repetitive interactional patterns within the family along five interrelated dimensions: structure, resonance, developmental stage, identified patienthood, and conflict resolution.

(i) Structure

This refers to the organizational aspects of the repetitive patterns of interaction within the family. Three specific categories of family organization are examined: leadership, subsystem organization, and communication flow.

Leadership assesses the distribution of authority and responsibility within the family. This category includes (i) hierarchy (Who takes charge of the family's directorship? Is leadership in the appropriate hands? Is it shared? Is hierarchy appropriate with respect to age, role and function?); (ii) behavior control (Who keeps order, if anyone? Are attempts to keep order successful or ignored?); and (iii) guidance (Who provides advice and suggestions? Does the advice provided have an impact on family interaction?).

Subsystem organization is concerned with the formal and informal organization of the family system, including (i) alliances (Who supports whom? Are dyad members closer to each other than to the rest of the family? Are alliances appropriate?); (ii) triangulations defined as an interference by family member C in a conflict between family members A and B, where C acts as an intermediary between A and B and where such interference causes a detour away from the original conflict; and (iii) subsystem membership (Who is a member of which subsystem? Are subsystems comprised appropriately with respect to age and function? Are subsystem boundaries clearly defined?).

Communication flow is concerned with communication flow within the family. The following aspects of the quality, quantity, and direction of communication are assessed: (i) directness of communication (Do individuals communicate directly with each other?); (ii) gatekeepers—switchboard operators (Is there a gatekeeper who controls, directs, or channels communication flow?); and (iii) spokesperson (Is there a family member who speaks for others in the family or for the whole family?).

(ii) Resonance

This is a measure of subsystem differentiation which takes into account the threshold of each family member's sensitivity to one another. At one extreme, boundaries can be either extremely rigid or impermeable (lack of connectedness). At the opposite extreme, they can be too overinvolved. Both of these extremes are considered maladaptive. (This view may be contrasted with functional family therapy in which the interpersonal relatedness needs, i.e., functions, are not considered to be maladaptive.) Ideally, there is a midpoint which allows for permeability, such that interaction and communication are possible at appropriate times, while retaining adequate differentiation and separateness.

In assessing resonance, allowances must be made for the cultural background of the family (Kurtines & Szapocznik, 1996). However, when behaviors result in symptoms, they are considered problematic whether or not they are culturally sanctioned. For example, some families or relationships may be characterized by machismo, manifested as an uncertainty of a man's feelings towards his wife and a nonverbal expression that replaces communication in the form of sexually forcing himself onto his wife. In this extreme and stereotyped example of machismo, even if machismo is cultural, this pattern of behavior would clearly be viewed as maladaptive.

(iii) Developmental stage

This refers to the appropriateness of family members' interactions with respect to roles and tasks assigned to various family members, taking into consideration their age and position within the family. The following sets of roles and tasks are considered in examining this dimension. Parenting roles and tasks: Are parents parenting at a level consistent with the age of the children? For example, are controlling and nurturant functions in accordance with child's age and stage of psychological development?

Spousal roles and tasks: Are spouses parenting at cooperative and equal levels of development? Child/sibling roles and tasks: Do the children function competently for their age and have appropriate rights and responsibilities? Extended family member's roles and tasks: In extended families, are parents able to assume proper parental position relative to their children in light of the role of their own parents and other relatives?

It is noteworthy that the major flare-ups in family stress and conflict are likely to emerge at times when developmental milestones are reached, because these occasions expose the families to unexpected demands which stress the family. Frequently, as the family responds in old ways to the new emergent situation represented by a developmental milestone, crises at the interface between homeostasis and flexibility often propel the family to seek help.

(iv) Identified patienthood

Identified patienthood (IPhood) refers to the extent to which the family is convinced that their primary problem is all the fault of the person exhibiting the symptom. Thus, IPhood refers to the extent to which the family places the identified patient (IP) and the patient's identified problem to be the sole problem of the family and uses that IPhood as a means of maintaining family homeostasis. There are five signs indicative of strong IPhood: (i) negativity about the IP—statements to the effect that the IP is seen as the sole cause of family pain and unhappiness; (ii) IP centrality—the IP is frequently the center of attention and topic of conversation and interactions; (iii) overprotection of the IPhood—family avoids confrontation with IP dysfunction by excusing it, explaining it away, minimizing it, or feeling that there is nothing that can be done about it ("That's just the way they are."); (iv) nurturance of IPhood—the IP dysfunction is supported or abetted by other family members, for example, a sibling does the homework for an IP who skips school; and (v) denial of other problems—statements implying that the IP is causing problems and pain coupled with statements that there are no other family problems ("We would be a happy family if it wasn't for the IP's problem.")

(v) Conflict resolution

This is a measure of the family's style in managing disagreements. It is important to observe the handling of differences and disagreements in a variety of situations since various situations, differing in the level of inherent conflict or level of emotionality, may be handled differently. There are five conflict resolution styles identified: (i) denial—disagreements are not allowed to emerge and situations are structured to prevent different opinions or critical opinions, or redefined to prevent the emergence of conflict; (ii) avoidance—disagreement begins to emerge but is stopped, masked, or strongly inhibited in some way, for example, "Let's not have a fight now," "You're so cute when you're mad," "That's not really important"; (iii) diffusion—moving from one disagreement to another without letting any emerge fully or making personal attacks which are not part of the conflict issue; (iv) emergence without resolution—separate accounts and opinions regarding one disagreement are clearly expressed but no solution is negotiated; and (v) emergence with resolution—separate accounts and opinions regarding a single disagreement are clearly expressed and a single final version or solution acceptable to all family members is negotiated.

There is considerable debate as to which of these conflict resolution styles is most adaptive and successful. From a family systems, communication theory, and psychoanalytic point of view, it might be possible to order these conflict resolution styles from least to most healthy as follows: denial, avoidance, diffusion, emergence without resolution, and emergence with resolution. However, from a more strategic perspective, it can be suggested that different styles may be adaptive at certain times. As demonstrated by Greenwood et al. (submitted for publication; see also Szapocznik & Kurtines, 1989), considerable judgement is recommended in determining what is an appropriate mode of conflict resolution given the overall circumstances confronted.

5.07.5.3 Clinical Formulation in Family Systems Therapy

"Assessment" refers to the process of conducting a systematic review of the molecular aspects of family interaction to identify specific qualities in the patterns of interaction of each family. That is, assessment identifies the strengths and weaknesses of family interactions. In contrast, clinical formulation refers to the process of integrating the information obtained through assessment into molar processes that characterize the family's interactions (c.f., Szapocznik & Kurtines, 1989). In individual psychodiagnostics, clinical formulation explains the presenting symptom in relationship to the individual's psychodynamics. Similarly, clinical formulation in family systems, therapy explains the presenting symptom in relationship to the family's characteristic patterns of interaction.

In FST therapy, assessment and clinical formulation are essential components of the intervention model, and are thus guided by a unitary clinical theory. For this reason, the way in which the information gathered from assessments is combined differs across systemic approaches. This means that, depending on the treatment model, certain aspects of family interaction will receive extensive consideration and other aspects will receive less attention. For example, in FFT, the therapist's clinical formulation will always include a description of the way in which the youth's problem behaviors are meeting interpersonal relatedness needs; whereas, in SFT the therapist's clinical formulation will always include an articulation of the way in which disturbances in family interactions (i.e., structure, resonance, etc.) give rise to, or maintain, problem behaviors.

A variety of factors influence clinical formulation. Although not included in the assessment, information that can help contextualize family interactions is required for clinical formulation. For example, in assessment the appropriateness of each family member's developmental level is evaluated. However, in clinical formulation, information on major family developmental transitions or events that occur within or outside the family are also considered because they help to explain why a symptom may bring a family into treatment at a particular time. Also important to clinical formulation is the chronicity of the patterns encountered, or conversely, the family's flexibility in adapting to internal or external changes. Such flexibility is an important indicator of the level of effort that will be required to bring about changes in the family system.

Individual as well as external systemic factors must also be considered in the clinical formulation. At the individual level, psychological factors such as beliefs, attitudes, intelligence, and psychopathology, as well as biological factors must be considered when evaluating the impact of family interactions on the problems experienced by the youth. Moreover, other systems may have a profound impact on the family, and consequently, must be considered in the clinical formulation (Dishion et al., 1995; Szapocznik, Kurtines et al., 1997; Tolan, Guerra, & Kendall, 1995). For example, the youth's interactions at school or with peers, or the nature of the neighborhood may serve as a powerful risk or protective factor. In addition, parents' extended family, friends, or work may serve as a source of strength or stress that may or may not contribute to the problems experienced by the youth (Szapocznik & Coatsworth, submitted for publication).

5.07.6 MEDIATORS OF CHANGE: MECHANISMS OF ACTION IN FAMILY THERAPY WITH ACTING-OUT YOUTH

One of the most interesting contemporary theoretical and research questions in FST, and psychotherapy research in general, is "what makes therapy effective?" It is of considerable interest that across the various models reviewed there appear to be certain common ingredients that contribute to their efficacy/effectiveness. This section highlights these common ingredients by reviewing existing in-session family therapy process research on the "mechanisms of action" involved in the successful treatment of behavior problem youth. In particular, the primary goal is to identify specific therapist and family processes that contribute to outcome.

In this review, we focus on existing empirical research rather than on theoretical articulations of the therapeutic process. Unfortunately, only a handful of studies have been conducted to identify the critical processes that are essential to effective family therapy. Because so much of this work has been conducted with problem behavior adolescents, this section is organized to present the presumed mediators of successful and unsuccessful outcomes with behavior problem adolescents. Whenever possible, however, we have attempted to integrate research and clinical theory from other work with children and adolescents.

Process research findings from three important domains of family systems therapy are presented in this section: (i) establishing a therapeutic alliance with adolescents and their family members, (ii) managing highly conflicted family interactions; and (iii) changing parent–adolescent and family interactions. Table 2 summarizes this research, and includes clinical recommendations to family systems therapists working with behavior problem youth and their families.

5.07.6.1 The Critical Role of the Therapeutic Alliance in Family Therapy

It is now generally recognized that the therapeutic alliance is an important variable in psychotherapy research and a strong

Table 2 Clinical recommendations for family systems therapy with behavior problem youth.

Clinical recommendation	*Reference*	*Future research questions*
Building alliance with behavior problem youth	Diamond & Liddle (1996)	(i) What strategies are most effective in building alliances with parent figures and other family members? (ii) Are individual or conjoint sessions more effective in building alliances with adolescents (or parent figures)? (iii) How does the alliance change over the course of therapy? (iv) What is the relationship between the adolescent alliance, the parent alliance, and changes in behavioral outcomes?
Present as an ally by showing support and by demonstrating ways in which you can assist in helping the adolescent meet her/his treatment (or personal) goals		
Collaborate with adolescent to formulate personally meaningful treatment goals		
Attend to the adolescent's experiences by reflecting their thoughts and feelings		
Reducing within-family negativity		
Selectively respond to family member negativity by asking questions about exceptions to negative attributions or statements	Melidonis & Bry (1995)	(i) What is the relationship between negativity in the treatment context and changes in family functioning or behavioral outcomes? (ii) Does reframing improve the therapeutic alliance? (iii) Does reframing produce similar results over the course of therapy? (iv) What is the relationship between intrapersonal (i.e., attributional) changes and interpersonal (i.e., interactions) changes?
Reframe negative attributions and expectations in a positive manner	Robbins, Alexander, Newell, & Turner (1996); Robbins, Alexander & Turner (1996)	
Reframe in the context of negative family interactions to minimize the escalation of negativity in the session		
In conjoint sessions, direct statements that orient family to treatment toward parent figures		
Handling resistance		
Approach resistance as interaction based, and adjust interventions during the engagement phase by using structural family therapy principles to overcome resistance to treatment	Szapocznik et al. (1989); Santisteban et al. (1996)	(i) What is the relationship between level of resistance and short-term (i.e., dropout) and long-term (i.e., behavioral changes) outcomes? (ii) Do different family members respond in a similar manner to therapist attempts to manage resistance? (iii) What are the therapist's structural maneuvers that encourage or discourage the family's (and specific family members') involvement in therapy?
Manage resistance by minimizing teaching or confrontive interventions, and by facilitating and supporting family members	Patterson & Forgatch (1985)	
Resolve therapeutic impasse by blocking and working through negative affect, and by amplifying thoughts and feelings that promote constructive dialogue	Diamond & Liddle (1996)	
Changing parent–adolescent interactions		
Focus on improving parental leadership, family subsystem organization, and communication flow	Robbins, Mitrani et al. (1996)	(i) What therapist interventions are most effective in changing parent–adolescent interactions? (ii) Are individual sessions with parent figures or the adolescent necessary to facilitate changes in parent–adolescent interactions? (iii) What is the relationship between the therapeutic alliance and changes in family interaction?
Focus on facilitating the expression and resolution of within-family disagreements		
Focus on improving parenting practices, including positive discipline, monitoring, limit setting and communication, and consistency between parents	Schmidt et al. (1996)	

predictor of therapeutic outcome (Bordin, 1979; Dierick & Lietaer, 1990; Gaston, 1990; Hatcher, Barends, Hansell, & Gutfreund, 1995; Horvath & Luborsky, 1993; Lambert, Shapiro, & Bergin, 1986; Luborsky, Barber, & Crits-Christoph, 1990; Safran, Crocker, McMain, & Murray, 1990; Waterhouse & Strupp, 1984; Weinberger, 1995). While most conceptualizations of common factors in psychotherapy suggest that the therapeutic bond is important in all psychotherapies (Orlinsky, Grawe, & Parks, 1994), most of the research on alliance to date has focused on individual therapy. The individual psychotherapy literature indicates that the alliance itself has a direct therapeutic effect (Henry, Strupp, Schacht & Gaston, 1994; Lambert, 1992; Strupp & Hadley, 1979) in both long and short-term therapies, and appears to operate within treatments from many therapeutic orientations, including the more behavioral therapies in which the alliance is not as likely as in analytic therapies to be overtly mentioned as a therapeutic goal (Eaton, Abeles, & Gutfreund, 1988; Gaston, Marmar, Gallagher, & Thompson, 1991; Gomes-Schwartz, 1978; Horvath & Symonds, 1991; Koss & Shiang, 1994; Krupnick, Sotsky, Simmens, & Moyer, 1992; Muran et al., 1995).

The therapeutic alliance also appears to be an important predictor of the outcome of clients in non-individual treatment modalities (Gaston & Schneider, 1992; Henry et al., 1994; Pinsof & Catherall, 1986). In specific reference to family therapy, Gurman & Kniskern (1978) concluded that "the ability of the therapist to establish a positive relationship ... receives the most consistent support as an important outcome-related therapist factor in marital and family therapy" (p. 875). In their review of family therapy research, Friedlander, Wildman, Heatherington, and Skowrow (1994) assert that components of alliance in family therapy have been predictive of session effectiveness, continuation in treatment, and therapeutic outcome. Although these reviews assert that the therapeutic alliance is critical in family therapy, few studies have been specifically designed to examine the impact of alliance in family therapy. In fact, DiGiuseppe, Linscott, and Jilton (1996) note that process research on the therapeutic alliance in therapy with youth in general is alarmingly scarce.

5.07.6.1.1 Building an alliance with behavior problem youth: specific recommendations

Diamond and Liddle (1996) examined the relationship between specific therapist engagement interventions and the strength of the therapist–adolescent alliance in multidimensional family therapy with drug using adolescents. In this study, therapist interventions and family alliance were rated in first and third sessions of five cases that showed the most improvement in alliance and five cases showing the least improvement in alliance. Results indicate that differences between the improved and unimproved groups do not appear until the third session of therapy. In session one, therapists try equally hard to engage reluctant adolescents. By session three, however, therapists in the improved alliance group were "formulating goals" "presenting themselves as an ally," and "attending to the adolescent's experience" significantly more than therapists in the unimproved group. Therapists in the unimproved group were "orienting adolescents to the collaborative nature of therapy" more than therapists in the improved group, though in both groups this intervention decreased over the first three sessions. These results are consistent with the assertions of other researchers who assert that although these factors are important, adolescents are particularly concerned with being involved in establishing the goals and tasks of therapy (DiGiuseppe, et al., (1996).

5.07.6.2 Reducing Within-family Negativity

Negativity, in the context of family functioning, has been heavily implicated in adolescent drug use and behavior problems. Research has shown that high levels of negativity interfere with effective problem solving and communication within the family (Alexander, Waldron, Barton, & Mas, 1989; Margolin, Burman, & John, 1989). These processes appear to play a similar role in the process of therapy itself, with numerous examples linking negativity in the therapy session to poor therapy outcome. Alexander, Barton, Schiavo, and Parsons (1976), for example, found that the ratio of negative to supportive statements was significantly higher in cases that dropped out of therapy than among cases that completed treatment. In turn, premature termination predicted recidivism in adolescents. In the same study, among the families that completed therapy, a reduction in family member negative behaviors during treatment was associated with positive outcome. Greater rates of within family disagreements have also been shown to be characteristic of noncompleters in structural-strategic family therapy (Shields, Sprenkle, & Constantine, 1991). A comprehensive review of the process of family therapy concluded that, in general, negativity may be predictive of premature termination (Friedlander et al., 1994).

5.07.6.2.1 Examining the impact of therapist interventions on within family negativity

Melidonis & Bry (1995) examined the effects of therapist questions about exceptions to family member statements on rates of blaming and positive statements in four families seen in a crisis unit for disruptive adolescent problem behaviors. They demonstrated that the therapist's use of exceptions questions was associated with a decline in blaming statements and an increase in positive statements.

Robbins, Alexander, Newell, & Turner (1996) examined the impact of specific types of therapist intervention (e.g., reframing, reflection, and organizational) on family members' negative attitude during the initial session of family therapy with a delinquent adolescent. Results revealed that: (i) across all therapist's interventions, adolescents were significantly more negative than mother's following therapist behaviors, but (ii) adolescents' attitudes improved from negative to neutral following therapist reframes but not other therapist interventions.

In a follow-up investigation, Robbins, Alexander, & Turner (submitted for publication) further examined the impact of therapist interventions on family processes. Similar to the previous study, the immediate effects of therapist reframing, reflection, and structuring interventions on family member behaviors were compared; however, only those therapist interventions that followed family member negative statements were included in the analysis. Results demonstrate that for this sample: (i) reframing is more effective than reflection and structuring statements in reducing family member negative behaviors; (ii) the results expanded the previous finding that adolescents respond more favorably to reframes than do mothers and fathers, now providing evidence of the effectiveness of reframing interventions for all family members; and (iii) adolescents responded more favorably to therapists (regardless of intervention) than did family members during negative exchanges.

These results demonstrate that highly negative and conflicted family interactions may be modified by therapist interventions in the treatment context. In particular, in the context of highly conflicted interactions, interventions that are positive and nonblaming appear to have a powerful effect on negative family interactions. These results are particularly evident for the adolescents in these samples, which is particularly promising given their highly negative and oppositional style when interacting with other family members and the therapist. Future research must attempt to link these changes in in-session conflict and negativity to other therapeutic changes and to the ultimate outcome of therapy.

5.07.6.3 Changing Parent–Adolescent Interactions

One of the core factors that consistently emerges in most etiological explanations of adolescent behavior problems is poor parenting and/or parent–child relationships. Aspects of the parent–child relationship that increase vulnerability to adolescent behavior problems include: lack of warmth and involvement, poor communication, lack of support, emotional distance, rejection, and lack of parental management (Kazdin, 1993, 1995; Kumpfer, 1989; Rutter & Guller, 1983; Werner & Smith, 1992; Widom, 1989). Research has also demonstrated that other parent and family factors, such as a lack of parental monitoring (Baumrind, 1991a, 1991b; Patterson & Dishion, 1985), harsh discipline, observed marital conflict, reciprocated negative communications, chronic parent–child conflict, and intense and frequent negative emotional expression (Alexander, 1973; Block, Block, & Keyes, 1988; Kandel, Kessler, & Margulies, 1978; Krinsley & Bry, 1991; Liddle & Dakof, 1995b; Rutter, 1980), play an important role in placing adolescents at risk for behavior problems (Hawkins, Catalano, & Miller, 1992; Jessor, 1976; Patterson, 1982; Simcha-Fagan, Gersten, & Langer, 1986). There is also an extensive literature indicating that changes in parenting practices positively impacts children's problem behaviors (for review see Estrada & Pinsof, 1995).

Support for the utility of interventions targeting the parent–child relationship in the context of family therapy comes from several sources. Parsons and Alexander (1973) found that positive modifications in parent–adolescent communications were associated with reduced recidivism (Alexander & Parsons, 1973) as well as a marked reduction in future offending by siblings (Alexander et al., 1976). In one study, Schmidt, Liddle, and Dakof (1996) linked improvements in parenting to reductions in drug abuse and behavior problems.

5.07.6.3.1 Changes in family interactions in successful and unsuccessful outcome cases

Robbins, Mitrani, Zarate, Coatsworth, & Szapocznik (1996) examined family interactions over the course of therapy in successful and unsuccessful cases to determine if changes in theoretically meaningful family interactions mediated treatment outcome. Four cases were selected that met the following criteria: case 1 showed improvement on measures of conduct disorder and had "good" pretreatment family functioning; case 2 showed improvement in conduct disorder and had "poor" pretreatment family functioning; case 3 showed no improvement and had "good" pretreatment family functioning; and case 4 showed no improvement and had "poor" pretreatment family functioning.

Results indicate that for families that showed improvement on measures of conduct disorder (cases 1 and 2), regardless of pretreatment family functioning, positive changes in family interaction were observed over the course of treatment; while for families that showed no improvement (cases 3 and 4), family functioning did not change, or worsened, over the course of treatment. These results provide limited but important support for the family therapy tenet that changes in family interaction mediate outcome. Moreover, these results highlight the importance of examining the therapeutic processes to understand those factors that contribute to successful therapy.

5.07.6.3.2 Family members' resistance to change

The results presented above suggest that family interactions play a critical mediating role in therapy with substance abusing, behavior problem youth. Attempts to change family interactions are often met with considerable resistance in therapy. For example, therapists appear to encounter the most "resistance" during the phase of treatment in which they are attempting to restructure family interactions (Chamberlain, Patterson, Reid, Kavanagh, & Forgatch, 1984). Therapists must successfully negotiate in-session "resistance" to achieve positive treatment outcomes.

Several important therapy traditions have viewed the therapeutic system's role in resistance and examined what therapists can do to prevent or manage resistance in family therapy. Resistance can be considered as a family characteristic or as a family response to an interaction with the therapist (Szapocznik & Kurtines, 1989; Szapocznik et al., 1989). Hence, at least in family systems thinking, the term "family resistance" fails to capture the systemic nature of the therapist–family relationship (Santisteban et al., 1996). This theoretical work and the empirical research of Patterson and colleagues, Alexander and colleagues, and Szapocznik and colleagues clearly demonstrate that so called family "resistant" behaviors appear to be elicited in interactions with the therapist, and as a result can be modified by altering the therapist's behaviors. For example, Patterson and Forgatch (1985) examined the immediate impact of therapist interventions on client noncompliance in families with a conduct disorder youth. The results of this study showed that therapist teach and confront were associated with increased noncompliance, whereas therapist facilitate and support were associated with decreased noncompliance. Reframing yielded mixed results.

Diamond and Liddle (1996) examined patterns of therapist's interventions and family interactions necessary to resolve therapeutic impasse in multidimensional family therapy with substance abusing youth. Impasse was defined as negative exchanges that thwart the therapist's attempts to facilitate parent–adolescent negotiations. This study demonstrated that families (in general) declined in functioning from the impasse phase to the intervention phase; however, families who successfully resolved the impasse improved their level of functioning following the impasse. Unsuccessful families, on the other hand, were initially more conflicted and pessimistic than successful families, and declined in functioning after the impasse. Results also indicated that therapists played a critical role in resolving parent–adolescent impasses. In successful resolutions, therapists were able to create an emotional treaty among family members by blocking and working through families' negative affect, and by amplifying thoughts and feelings that promoted constructive dialogue. Finally, adolescents became more cooperative and engaged in therapy when parents shifted from trying to control them to trying to understand them.

Taken together these results provide specific recommendations for handling "resistant" behaviors in family therapy. In particular, resistant behaviors must first be reconceptualized as part of an interaction with the therapist. Adopting this view permits the therapist to examine their own contribution to resistance and opens up possibilities for strategically altering their own behavior to influence family members. Therapist facilitative, supportive, and reframing interventions may be particularly useful when "working through" so-called resistant interactions. Likewise, therapist interventions that block negative affect and/or promote constructive dialogue appear to decrease resistant interactions in family therapy.

5.07.6.3.3 The relationship between changes in parenting behaviors and adolescent behavioral outcomes

Schmidt et al. (1996) examined in-session processes in multidimensional family therapy to determine: (i) the nature and extent of change in the behavioral, affective, and cognitive features of parenting; and (ii) the link between parental subsystem changes, and reduction in adolescent substance use and behavior problems. Results demonstrated significant decreases in negative parenting practices and significant increases in positive parenting features. Analyses with adolescent drug use and behavior problem scores indicated a significant relationship between parent improvement and reduction in drug use and acting out. These results demonstrate that not only are parenting behaviors amenable to therapist interventions, but that changes in parenting behaviors in family therapy are associated with changes in relevant adolescent behavioral outcomes. In fact, this relationship was evident in almost 60% of the families in this sample.

5.07.7 SUMMARY AND FUTURE DIRECTIONS

Although FST has emerged as a treatment of choice in the treatment of some child and adolescent clinical populations, the field lacks a solid empirical base demonstrating the efficacy and effectiveness of family systems interventions for a variety of clinical disorders of youth. With the exception of work with behavior problem youth, including substance abuse, family systems treatments have flourished in clinical rather than research settings. Thus, there is an obvious need to bridge the clinical–research gap in FST with childhood disorders.

Research also must be conducted to elucidate the important mechanisms of action in FST. At a molar level, this research should examine universal processes across theoretical models and clinical populations to shed light on what may be the "core" ingredients of FST. However, at a micro level, research must also provide therapists with specific clinical recommendations about how to work with youth and their families. That is, because therapists must respond to family members in the context of their present interactions in therapy, process research can assist clinical model developers in generating or testing the positive or negative impact of particular therapeutic interventions on immediate and long-term outcomes. With respect to immediate and long-term outcomes, such research can also help describe the shape or trajectory of change in FST. The development of new statistical procedures, such as hierarchical linear modeling (Bryk & Raudenbush, 1992; Raudenbush, 1993) and latent growth curve analysis (see Burchinal, Bailey, & Snyder, 1994; Speer & Greenbaum, 1995), will permit research to examine complex clinical theories about the nature of change.

Other challenges face family systems theorists and researchers. For example, family systems therapists are increasingly acknowledging the interface between the family and the environment, and the complexity of factors that influence individual development (Dishion et al., 1995; Henggeler & Borduin, 1990; Szapocznik et al., 1997; Tolan et al., 1995). This recognition has led to the development of a new wave of multisystemic/ecosystemic interventions targeting interactions in (and between) many systems. The fact that most of these interventions have emerged in inner city contexts has illuminated a variety of other challenges that family systems therapists and researchers must address, such as: (i) working with ethnically diverse and the urban poor populations, (ii) confronting the deteriorating neighborhoods in which these families reside, and (iii) challenging conventional methods of service delivery (e.g., location of treatment). Such challenges will require considerable perseverance and ingenuity from the therapists who work in these contexts, and for the researchers who must attempt to shed light on the efficacy and effectiveness of this work and to understand how the change process unfolds.

A final challenge involves the considerable clinical skill and sophistication that is required to implement FST. It should be apparent from the discussion of FST in this chapter, that the therapist is required to recognize the nature of the interactions at every moment in therapy—and to track the evolving process as it unfolds. Moreover, the therapist must be able to intervene by strategically selecting, from a complex set of interventions, the intervention that will most effectively move the family toward the therapeutic goal of the intervention model at that point in time (e.g., engaging, building alliances, reducing negativity, or changing parenting). Traditionally, it has not been fully recognized that the teaching and learning of FST is a rather laborious process that requires education about the key concepts of the family process paradigm and the complex interpersonal skills required to facilitate change in the FST context. Moreover, training also requires an extensive apprenticeship in which new therapists can see families under intensive supervision. Recognition of the challenge of training and learning FST is critical if we will ever be able to transfer research findings into clinical practice. One of the great factors impeding this research to practice translation has been the lack of recognition of the considerable work involved when training and supervising therapists who participate in research projects; training which must be replicated at the service level if we are ever to translate our promising research findings into widespread clinical practice.

5.08.1 INTRODUCTION

Prior to 1965, most attempts to treat childhood behavior problems focused exclusively on the child. Approaches included outpatient play therapy and inpatient child therapy. Since the mid-1970s, however, there has been a shift in treatment philosophy for child conduct problems from an exclusive focus on the child to recognition of the primary social context in which the child lives—that is, the family. As a result, parent training (PT) has become an integral part of services for many childhood disorders including autism and developmental disabilities (Schreibman, Kaneko, & Koegel, 1991); academic, learning and language delays (Laski, Charlop, & Schreibman, 1988); externalizing problems such as attention deficit disorder (Anastopoulos, Barkley, & Sheldon, 1996); oppositional and conduct disorders (Forehand, Steffe, Furey, & Walley, 1983; Patterson, Chamberlain, & Reid, 1982; Webster-Stratton, Kolpacoff, & Hollinsworth, 1988); and internalizing disorders such as fears and anxiety disorders (Barrett, Dadds, & Rapee, 1993). PT is also widely used with abused and neglected children as a component of a multifaceted intervention (Lutzker, 1992), as well as for maritally distressed parents (Dadds, Schwartz, & Sanders, 1987) and for parents who are divorced (Grych & Finchman, 1992). This extensive empirical base supports the hypothesis that when parents are trained to implement behavior change strategies, there is a corresponding improvement in their parenting interactions, which in turn results in improvements in children's social and emotional adjustment.

PT is a generic term used herein to refer to forms of intervention for child behavior problems in which parents are trained to work with their children. In this approach parents are not only included in the therapeutic process, they are utilized as cotherapists working under the guidance of the therapist to invoke change in their child's behavior. The training focuses on altering parents' perceptions, attributions, affect, and parenting behaviors toward their children. The term "parent training" is used here in preference to other terms such as "family management training," "parent–child interactional training," or "functional family therapy" to more accurately reflect the fact that in PT it is the parents who are the targets of the treatment and prevention efforts. PT is an empirically supported, therapeutic process based on the twin assumptions that, since parents are the primary socializing agents in their children's lives, parenting practices are important—sometimes the critical determinants—in the development and maintenance of many maladaptive child behaviors and, more importantly, that positive parenting practices are the key to facilitating and maintaining positive changes in child behavior.

There are many versions of PT, but they all share several characteristics in common. First, it is the parents who are trained; there is no direct intervention with the children. Second, parents are taught to identify, observe and define behaviors they want to increase or decrease. Third, parents learn social learning principles including positive reinforcement (e.g., praise and incentive programs) and discipline strategies (e.g., ignoring, loss of privileges, time out). Fourth, they are taught these approaches by means of interactive discussion, modeling, role playing, videotape demonstrations, home assignments, and direct feedback.

A number of theories about the socialization of behavior and emotion have shaped the specific methods, goals, content, and therapeutic process of different PT programs. A parent's function may be formulated as a teacher, coach, model, relational partner, attachment figure, or proximal gatekeeper for the larger environmental conditions; and each shift in emphasis brings a somewhat different focus for PT. Moreover, as current theories of child psychopathology have become more developmental in perspective and ecological in scope, PT has drawn from and integrated a number of theoretical perspectives, from general theories of learning and development to specific research areas and agendas. The evolution of PT from an operant behavioral approach to a model which includes relational, affective, and even broader ecological factors has brought a broader theoretical base, one that incorporates multiple theoretical approaches.

5.08.1.1 General Theoretical Underpinnings

PT draws from and includes theories of learning, theories of therapeutic change, and theories of child social and emotional development. The theoretical mainstays of PT can be, and often have been, subsumed under three general areas: (i) social learning theory, which includes behavioral and cognitive-behavioral views; (ii) "relational theories" such as attachment and psychodynamic theories; and (iii) a family systems perspective which includes the parent–child and other familial relationships. In addition, extensive research in child development has provided PT programs with a framework of empirically-based models of normal and pathological child development.

5.08.1.2 Contributions from Social Learning Theory

Contemporary PT has its roots in applied behavior analysis, models of operant behavior (Baer, Wolf, & Risely, 1968), and social learning theory (Bandura, 1977). A key assumption is that children's behaviors are learned from their interactions with significant persons in their lives, particularly their parents. Child problem behaviors—be they internalizing problems, such as fears and anxieties, or externalizing problems, such as defiance and aggression—are thought to be maintained by environmental reinforcements. The focus of PT from this perspective is on changing maladaptive child behaviors by changing the environmental contingencies which maintain these problem behaviors. For example, to take an internalizing problem such as a social phobia or separation anxiety, research has suggested that family interactions play a role in the development and maintenance of these fears (Kendall, 1992); parents may inadvertently reward anxious behavior by their attention as well as by removing aversive stimuli such as household chores or permitting a child to stay home from school (King, Hamilton, & Ollendick, 1988).

Therefore, this approach emphasized the importance of parents as "behavior change agents" for their children (Patterson, 1982; Patterson, Cobb, & Ray, 1973; Wahler, 1976). Parents were taught specific parenting strategies such as child-directed play, praise and tangible reinforcement, and discipline approaches such as ignoring misbehavior, time out and response cost. These parenting behaviors and strategies helped parents avoid negative reinforcement traps and coercive interactions with their children (Patterson, 1982, pp. 27, 28) as well as positive reinforcement traps (Wahler, 1975) which were thought to lead to escalating child behavior problems. Likewise, this conceptualization has been particularly useful and relevant for child externalizing problems. Research has demonstrated that parents of antisocial children do engage in particular parenting practices which promote aggressive behavior (through attention and compliance to child coercive strategies) and suppress prosocial behavior (by ignoring or even providing aversive consequences) (Hinshaw & Anderson, 1996; Patterson, 1982, 1986).

Social learning theory (Bandura, 1977) posits that behavior is learned not only by experiencing the direct consequences of those behaviors, but also by observing similar behavior and its consequences. Thus, Bandura emphasized the importance of parents "modeling" appropriate social interactions for their children, since children learn by watching their parents interact (with each other and with others), and not just by their responses to the child's own behaviors. Behavioral models are particularly potent when they are persons of higher social status, such as parents, teachers, and older peers, and when their acts are perceived to be rewarded or accepted (Bandura, 1977). Again, the research supports this modeling theory in studies which have shown that children with high levels of fears and anxieties are more likely than nonfearful children to have anxious or fearful parents (Kendall, 1992), as well as studies showing that aggressive children are more likely than nonaggressive children to have parents who use aggressive discipline or who are antisocial themselves (Patterson, DeBaryshe, & Ramsey, 1989).

In accordance with this social learning model, then, PT programs are aimed at helping parents identify and isolate their children's prosocial (or appropriate) and maladaptive (or inappropriate) behaviors, change the reinforcement contingencies, and implement rewards for positive behavior and sanctions for negative behavior. The general purpose of PT from this perspective is to alter the interactions between parents and children so that prosocial behavior rather than coercive behavior is modeled and reinforced by parents (Kazdin, 1987). Social learning theory informs PT's methods as well as content, using live and videotape modeling, role play and rehearsal of new skills, home practice assignments, and direct reinforcement (social and tangible) of parents for their achievements during training.

5.08.1.3 Contributions from Cognitive Psychology

Other theoretical perspectives helped expand our understanding of not only the importance of training parents to change their behavior responses to children but also the importance of influencing parents' perceptions, affect, and cognitions about their children. Cognitive psychology, in particular, focuses on the meanings we make of life events, and how those meanings influence our motivation, behavior, and ability to change. Cognitive events such as attributional biases, self-efficacy beliefs, and negative self-statements influence the course of psychopathology as well as the ability to parent effectively. Bandura proposed that central to parents' ability to change their behavior is their belief about their own self-efficacy (Bandura, 1982)—that is, their belief about the degree to which they can be successful with their children. Attribution theory (Smith & O'Leary, 1995) and learned helplessness theory (Abramson, Seligman, & Teasdale, 1978; Folkman & Lazarus, 1988; Seligman, 1975) are other cognitive theories that posit the importance of beliefs and expectations in influencing parents' interactions with their children.

These expanded theoretical perspectives led to a blending of cognitive and behavioral theories and a concomitant shift in PT known as the cognitive-social learning approach. The cognitive-social learning approach treats cognitions as covert behaviors, subject to the same laws of change as more overt behaviors, and hence appropriately examined, isolated, and differentially reinforced (Meichenbaum & Turk, 1987) as part of the PT process. For example, if parents perceive their children as more powerful than themselves, as motivated and able to hurt them, perhaps even predicting when their child is young that their child will become a juvenile delinquent, those parents are less likely to respond to their child's misbehavior in a positive and consistent manner. Furthermore, parents' negative expectations for a child may become a self-fulfilling prophesy, influencing the child's own self-perceptions and expectations. Parents are often unaware of how their beliefs about their own powerlessness relative to their child can undermine their parenting interactions—resulting in poor limit setting, withdrawal from conflict, lack of structure, and further loss of control. Out of this school of thought have come adjuncts to PT including training for parents in coping via self-statements, problem-solving techniques, stress management, and self-reinforcement strategies.

5.08.1.4 Contributions from Relational Theories

In the category of relational theories attachment theory and psychoanalytic theory are included because of their central concern with emotion, affective processes, and the quality of relationships. Although a more positive parent–child relationship is expected to result from improved parenting strategies, an articulated relational theory did not initially inform PT. Qualitative aspects of parent–child interactions were only indirectly acknowledged. For instance, even in those few behavioral programs which did include training for parents in child-directed play skills, the purpose of this training was to increase the reinforcing power of parental attention; improving relationships was merely a secondary benefit (Forehand & McMahon, 1981). However, as PT expanded beyond its operant focus, child-directed play therapy became a technique and a source of theory concerning the affective and relational aspects of parenting (Eyberg & Boggs, 1989), as separate from behavioral management. Within a relational focus, PT aims to increase parent–child bonding by teaching parents techniques for increasing their positive interactions with their child—as a goal in itself. The emphasis is on increased expression and communication of positive affect, including love, affection, acceptance, enjoyment, and empathy as well as increasing parents' pleasure in their children and enjoyment of play with them. Another aspect to PT that grows out of relational theory is training parents in how to respond to children's expression of emotions as well as how to manage their own emotions. This renewed interest in affective processes reflects a growing recognition from the research that a parent's emotional expression and regulation are likely to affect the quality of their children's emotional language, which in turn affects the quality of their social relationships and ability to self-regulate in the face of conflict.

5.08.1.5 Contributions from Family Systems Theory

Current PT programs have also been influenced by family systems theory. In this theoretical perspective, family factors are recognized as the larger context for parent–child interactions. From a family systems perspective, this means the focus of concern in PT is enlarged to include such factors as family roles, rules, and communication patterns, and those factors are conceptualized as family structures (Minuchin, 1974) and processes (Haley, 1976). A family systems perspective emphasizes the impact of these structures and processes on the parent–-child relationship and behaviors. Inherent in the treatment of families from the systems perspective is an understanding of how family dysfunction (e.g., marital conflict) impacts both parent and child functioning, and PT targets not just parenting behaviors but family interaction patterns (including parent–child, marital, and sibling relationships), family perceptions of individual members, as well as parents' memories of their family of origin and what they learned from that experience.

5.08.1.6 Emerging Perspectives

More recently, in the early 1990s, functional contextualism (Biglan, 1993) has led to our understanding of how social environment—such as stressful life events, socioeconomic status, racism, lack of support systems—influence parents' ability to maintain behavior change. At this point the influence of this perspective on PT programs is still slight, but therapists are beginning to consider factors such as these when designing programs for socioeconomically deprived families and families experiencing considerable life stress.

5.08.2 CHILD CONDUCT PROBLEMS

Despite some evidence suggesting that PT may be a useful treatment for children's internalizing disorders (see Sanders, 1996 for review), this chapter focuses on PT as a treatment approach for young preschool and school-age children with oppositional defiant disorder (ODD) and conduct disorder (CD), defined generically in this paper as conduct problems. We have confined our review of PT to the treatment of conduct problems because there exists a large body of programmatic research regarding the etiology and treatment of conduct problems and because comparatively less is known about the causes of internalizing disorders. Conduct problems frequently co-occur with other disorders such as attention deficit disorder, learning disabilities, language delays, and internalizing problems such as anxiety and somatization. Moreover, children with conduct problems frequently come from families who are experiencing considerable marital discord, depression, and distress. What we know about PT as an intervention for children with conduct problems may provide a paradigm for other less well-researched childhood disorders, including internalizing disorders.

5.08.2.1 Prevalence

Childhood conduct problems are the most frequently occurring disorder in both clinic-referred and general populations (Quay, 1986). Results of epidemiological studies have indicated that the percentage of young children meeting the criteria for the clinical diagnoses of ODD and CD ranges from 7% to 25%, with the prevalence varying according to the population surveyed (Campbell, 1995; Landy & Peters, 1991; Richman, Stevenson, & Graham, 1982). Even for preschoolers, relatively high proportions of parents complain of noncompliance, limited self-control, aggression, and poor relations with siblings and peers (Richman et al., 1982). In a study involving over 400 high-risk families in Seattle, Washington, Webster-Stratton (1995) reported that more than 25% of children scored above the 90th percentile for aggressive behaviors as reported by their mothers. In a large-scale screening study of day-care attendees (2–4 years old) in rural Vermont, Crowther, Bond, and Rolf (1981) found that at least 20% of the children exhibited high frequencies of aggressive and disruptive behaviors, with the greatest severity observed among preschool boys. Boys are two to three times more likely than girls to manifest conduct problems (Quay, 1986).

"Externalizing" behavior problems are characterized by high rates of hyperactivity, aggression, impulsivity, defiance, and noncompliance (Campbell, 1995; Campbell & Ewing, 1990; Robins, 1981). The greatest stability in preschool child behavior problems occurs among externalizing problems in contrast to internalizing disorders, which are age-specific and usually but not always remit over the course of development (Fisher, Rolf, Hasazi, & Cummings, 1984). A variety of studies have shown high continuity between behavior problems in the early preschool years and conduct disorders in adolescence (Egeland, Kalkoske, Gottesman, & Erickson, 1990; Richman et al., 1982; Rose, Rose, & Feldman, 1989). Campbell's (1991) review of a series of longitudinal studies of hard-to-manage preschoolers reveals a surprising convergence of findings. At least 50% of preschool children with moderate to severe externalizing problems continued to show some degree of disturbance at school age, with boys doing more poorly than girls. Of those with continuing behavior problems, 67% met diagnostic criteria for attention deficit hyperactivity disorder (ADHD), ODD, or CD at age 9. Moreover, Eyberg (1992) points out that this percentage may be an underestimate, since many of the most dysfunctional families were lost to follow-up.

Developmental theorists have suggested that there may be two developmental pathways related to conduct disorders: the "early-onset" vs. "late-onset" pathways (Patterson et al., 1989). The hypothesized "early-onset" pathway begins formally with the emergence of aggressive and oppositional disorders (ODD) in the early preschool period, progresses to aggressive (e.g., fighting) and nonaggressive (e.g., lying and stealing) symptoms of conduct disorders in middle childhood, and then develops into the most serious symptoms by adolescence, including interpersonal violence and property violations (Lahey, Loeber, Quay, Frick, & Grimm, 1992). In addition, there is an expansion of the settings in which the problem behaviors occur, from home to daycare or preschool, then to school, and finally to the broader community. For "late-onset" (adolescent-onset) conduct disorders, the prognosis seems more favorable. Adolescents who are most likely to be chronically antisocial are those who first evidenced symptoms of aggressive behaviors in the preschool years, followed by early-onset ODD or CD (White & Bailey, 1990). Children with early-onset ODD also account for a disproportionate share of delinquency in adolescence. Thus ODD is a sensitive predictor of subsequent CD, and the primary developmental pathway for serious conduct disorders in adolescence and adulthood appears to be established in the preschool period (Loeber, 1991).

The next section discusses theories regarding the etiology of conduct problems. These are important in terms of their implications for intervention, including PT.

5.08.2.2 Etiological Models

Theories regarding the causes of child conduct problems posit five different types of influence on child behavior: biological, attachment, family and parent–child interactions, sociocognitive, and environmental. Due to space limitations we will focus primarily on parental and familial models because of their clear implications for PT. However, it should be clear that by limiting our discussion of the biological, attachment, and sociocognitive models we do not mean these should be ignored and should not be enlisted when appropriate nor do we mean to imply that these are necessarily competing models. For instance, research indicates that biological and environmental factors are interrelated and transactional (Caspi & Moffitt, 1995). A more complete review of these models is available from the first author.

5.08.2.2.1 Biological model

Psychobiological research on child conduct disorders has lagged behind similar work on adult criminality and antisocial behavior, but is gaining recognition—particularly research concerning the temperamental, psychophysiological, and neurophysiological aspects of externalizing disorders. Still, many studies suffer from small or incompletely specified samples, lack of diagnostic specificity, and lack of longitudinal follow-up; there is a need for replication and cross-validation. The biological model argues that some abnormal aspect of the child's internal organization at the physiological, neurological, and/or neuropsychological level (which may be genetically transmitted) is at least partially responsible for the development of conduct problems. The most overt evidence for a biological component for children with ODD/CD includes the disproportion of boys to girls and the apparent heritability of antisocial traits, based on the high number of criminals in some families (Hutchings & Mednick, 1977). Adherents of this view have proceeded somewhat cautiously, lest they appear to be endorsing biological determinism. However, since the late 1980s a substantial body of research has been accumulating which supports the inclusion of biological factors in models of development and maintenance of conduct disorder (see Hinshaw & Anderson, 1996 for a review).

Biological explanations for antisocial behavior need not imply that an antisocial personality is biologically predetermined. Even biology is hypothesized to be subject to environmental impact. Biology in itself is only suggestive of a vulnerability to other risk factors (e.g., parental socialization influences) for antisocial behaviors. Furthermore, biological markers of antisocial behavior have thus far been isolated only for subsets of children with more extreme deficits, such as undersocialized aggressive conduct disorder, who are often doubly impaired with ADHD. We do not know what, if anything, biology has to contribute to our understanding of milder deficits. Lahey, Hart, Pliszka, Applegate, and McBurnett (1993) state clearly that investigation of biological variables such as neurotransmitters, brain imaging techniques, skin conductance, or hormonal influences does not imply that psychosocial factors have no role in the maintenance of childhood conduct problems. On the contrary, they postulate "that a socio-environmental event (e.g., abnormal infant experience) could be one of the causes of aggression, but that the effect of this experience on aggression is mediated by alterations in neurotransmitter activity" (Lahey et al., 1993, p. 142). Indeed, the amount of variance accounted for by biological factors appears to be relatively small. Factors such as family support, quality of parent management strategies and socioeconomic status appear to interact with the child's biology or temperament to influence outcome, again suggesting the mediating role of the child's microsystems.

The research findings regarding children with conduct problems who have such difficulties as low autonomic reactivity (Quay, 1993) have implications for how biological deficits may be amplified over time and for how parenting can exacerbate or minimize inherent deficits. For example, children with biological deficits are not as responsive to their parents' normal efforts to praise, reward, set limits, and impose negative consequences; they may even appear to their parents to be indifferent to their discipline attempts. This lack of responsiveness on the part of the child not only makes the child less reinforcing to the parent but also leads parents to feel the effects of their parenting approaches are unpredictable. As parents continue to experience a lack of success in parenting, they develop a low sense of self-efficacy, become more inconsistent in their parenting responses and sometimes resort to increased use of spanking and harsh punishment.

This theory suggests the need for PT programs which help parents understand their children's biological deficits (their unresponsiveness to aversive stimuli and heightened interest in novelty), and support parents in their use of effective parenting approaches so that they can continue to be positive and provide consistent responses. Parents who are concerned that their child is not responsive to praise or appears not to care about consequences can learn that this apparent invulnerability is a coping response for dealing with negative feedback about his or her behavior. The data regarding autonomic underarousal theory suggests that these children will require over teaching (i.e., repeated learning trials) in order to learn to inhibit undesirable behaviors and to manage emotion. They will need consistent, clear, specific limit setting that utilizes simple language and concrete cues and reminders. Their parents will need to rely on tangible reinforcement and novel reward systems, rather than punishment, and will need to help their children anticipate possible consequences. The research regarding these children's possible language and reading delays suggests the need to train parents in ways to help their children with verbal skills such as self-talk management, problem solving, and communication, as well as reading skills.

5.08.2.2.2 Attachment model

Bowlby's (1980) observations of neglected infants introduced us to a new way of understanding children's emotional development. Both his method and thinking have led to attachment theory as a model for describing and accounting for the effects of parent–child relationships. Studies of attachment relationships have focused on mothers and infants; young school-age children have been studied much less frequently. Rarely has the research concerned itself with father/child attachment relationships. Specific research regarding the connections between children's attachment status and the development of conduct problems is very much in its infancy.

Since the late 1980s, methods of measuring attachment beyond toddlerhood have been developed, with two new attachment paradigms targeted for preschool and early primary age children (Cassidy & Marvin, 1992; Main & Cassidy, 1987). Several studies utilizing those measures of attachment with young children have found relationships between insecure attachment and child aggressive behaviors (Greenberg, Speltz, & DeKlyen, 1993). However, attachment status on its own probably does not directly relate to conduct disorder, nor to any specific psychological disorder. The differences between high- and low-risk samples suggest that secure attachment serves as a protective factor in the presence of other risk factors for conduct problems (Dishion, French, & Patterson, 1995).

Finally, in postulating an association between early attachment and psychopathology, one must exercise caution. For attachment status interacts not only with parenting practices, but also emerges as a result of reciprocal interactions with other risk factors such as child biology and temperament, parent psychopathology and social stress. For example, an interaction of biology and attachment may operate as follows: for a certain subset of children with early-onset conduct problems, biology—that is, a difficult temperament—may underlie their difficulties in social learning and communication, both of which may influence mutual acceptance, leading to negative affect and attachment difficulties. In addition, parental depression has been shown to be linked to child attachment status (Radke-Yarrow, 1991; Speiker & Booth, 1988). Furthermore, both attachment and depression are related to parents' parenting skills. For example, in one study both insecurely attached mothers and depressed mothers were likely to retreat when their attempts to limit set with their children were met with resistance; they also showed more inappropriate use of affection. Finally, severe maternal depression, like other severe stressors, appears to be related to disorganized attachment status (Teti, Gelfand, & Messinger, 1995).

The concept of internal working models is helpful for PT programs because it focuses attention on the quality of parent–child relationships and the need for security and predictability in relationships. In the case of the insecurely attached child and parent, the model suggests the need for a more complex PT program involving a focus on relationship building, communications skills, cognitive techniques, and affect management skills. Along with parenting techniques, the insecurely attached parent will need to learn to control negative affect in the parent–child relationship and to communicate positive emotion such as empathy; beyond that, the parent may need help developing empathy and positive feelings for the child. PT can work with parents' perceptions of their child so that parents can recognize how their responses to their child's behavior may in a large part be based on their own past relationships with their parents and not on the child himself (Stroufe & Fleeson, 1986). The therapist's frequent articulation and expression of empathy during training for the parent and child as well as education about child development—specifically, the needs of difficult children—can help parents to understand their child's point of view. This change in perspective can ultimately lead to change in the parents' internal working model of the child, which can then lead to changes in the internal working model of the relationship for both the parent and child. PT for the insecurely attached child must also involve training the parent in attachment-promoting interactions, such as "child-directed play," a method of play which involves listening, following the child's lead, describing and reflecting on the child's actions, and praising and encouraging the child's ideas and behaviors. Daily child-directed play sessions influence the child's working model of the parent as well as the parent's working model of the child. Finally, the attachment perspective on PT suggests that the therapist's role is to provide a secure base for parents who are exploring new perspectives and models of relationships. By being consistent, predictable, empathic, accepting, and reinforcing, the therapist can provide the parent with a new working model, namely that of a supportive relationship.

5.08.2.2.3 Family functioning

Research findings have provided the impetus to expand our models to include other family and contextual variables, reflecting a broader systems view of family influences on children's behavior. Clear connections have been established between parental psychopathology (including antisocial behavior and depression), marital conflict and parenting interactions and child conduct problems.

(i) Antisocial behavior

Intergenerational linkages with respect to criminal behavior have been established for some time (Frick & Jackson, 1993), and there is considerable evidence associating certain types of parental psychopathology with childhood aggression and conduct problems (Patterson, 1982). Specifically, depression in the mother, alcoholism and substance abuse in the father (Frick et al., 1992), and antisocial and aggressive behavior in either the mother or the father (Faraone, Biederman, Keenan, & Tsuang, 1991; Frick, Kuper, Silverthorn, & Cotter, 1995) have been implicated as risk factors. An association has also been found between children's aggression and their parents' aggression at the same age (Huesmann, Eron, Lefkowitz, & Walder, 1984). In a prospective study of 171 clinic boys, parental antisocial personality disorder (APD) was a significant correlate of conduct problems, but the interaction of parental APD and the boys' verbal intelligence predicted the persistence of conduct problems over time (Lahey, Loeber, Hart, & Frick, 1995).

(ii) Depression

Depression—maternal depression in particular—has received a great deal of attention in terms of its influence on child adjustment. Children of depressed parents have been shown to be at increased risk for conduct problems (Downey & Coyne, 1990). Clinic mothers of children with conduct problems consistently rate themselves as more depressed (on the Beck Depression Inventory) than nonclinic mothers of typically developing children, suggesting a relationship between maternal depression and reported child behavior problems (Griest & Wells, 1983; Webster-Stratton & Hammond, 1988). Studies have suggested that depressed mothers make more negative appraisals of their children's behaviors (Schaughency & Lahey, 1985) than their spouses or nondepressed mothers (Webster-Stratton & Hammond, 1988). However, research (using direct observation) evaluating the relationship between depressed and nondepressed mothers' parenting behavior and their children's behavior has yielded conflicting conclusions. Some researchers (Hops et al., 1987; Rickard, Forehand, Wells, Griest, & McMahon, 1981) have found that depressed mothers of clinic-referred children use not more but fewer commands and criticisms than nondepressed mothers, while others have found maternal depression to be related to increased criticisms, spankings, and unsupportive or inconsistent parenting (Cunningham, Bennes, & Siegel, 1988; Webster-Stratton & Hammond, 1988). Still others have found no relationship between maternal depression and parenting behavior (Rogers & Forehand, 1983). Furthermore, the possible linkage between fathers' depression, parenting behaviors, and child conduct problems has not been explored in the research. Finally, it is important to recognize that depression is associated with other stress variables such as poverty, marital distress, and negative life events, making it difficult to determine what effects are attributable to depression *per se*.

The relationship between maternal depression and conduct problems has been conceptualized as follows: maternal depression results in negative appraisals of the child's behavior and contributes to a mother's negative responses (increased irritability, hostility, and punishment) to her child's misbehavior (Patterson, 1982). It has also been theorized that in response to an increase in maternal criticisms, the child displays an increase in noncompliance and other misbehaviors (McMahon & Forehand, 1984; Webster-Stratton & Hammond, 1988). These child misbehaviors further exacerbate the mother's depression, negative appraisals of the child and negative parenting behavior. Not only does the mother reinforce the child's misbehavior (through her negative attention), but the child learns more hostile and irritable behaviors through modeling the behavior of the depressed mother (Downey & Coyne, 1990). It has also been argued that depression contributes to the "coercive" cycle by resulting in decreased maternal attention for positive behaviors, decreased positive reinforcement, and lack of consistent supervision. In other words, depression results in the mother being emotionally unavailable and inattentive to the child. Thus maternal depression may indirectly lead to conduct problems as a result of negative reinforcement of inappropriate child behaviors, inconsistent limit setting, and emotional unavailability.

However, the association between maternal depression and child conduct problems is not adequate justification for concluding that depression "causes" child conduct problems. An alternative model could be postulated reversing the directionality—that is, the child's difficult and unpredictable negative behaviors are minimally reinforcing the mother's efforts, resulting in inconsistent and negative parenting responses; as the mother fails in her efforts to control the child's behavior, she becomes increasingly depressed. The research finding that maternal depression can improve with PT programs suggests that there is a three-way reciprocal interaction between the child's conduct problems, negative parenting style, and maternal depression. And as noted earlier it is highly probable that depression is linked to attachment status and that these two factors operate in some kind of synergy.

(iii) Marital conflict

In addition to depression in the parents, another family characteristic that has been found associated with the development of conduct problems is interparental conflict and divorce (Kazdin, 1987). In particular, boys appear to be more apt to show significant increases in antisocial behavior following divorce. However, some single parents and their children appear to do relatively well over time postseparation, whereas others are chronically depressed and report increased stress levels. Once researchers began to differentiate between parental divorce, separation, and conflict, they began to understand that it was not divorce *per se* that was the critical factor in the child's subsequent behavior and socioemotional development, but rather the degree and intensity of parental conflict (O'Leary & Emery, 1982). For example, children whose parents divorce but whose homes are conflict-free are less likely to have problems than children whose parents stay together but experience a great deal of conflict (McCord, McCord, & Thurber, 1962). Children whose parents divorce and continue to have conflict have more problems than children whose parents experience conflict-free divorce (Hetherington, Cox, & Cox, 1982) Moreover, intact families who seek help for child behavior problems commonly present high levels of marital strife (Johnson & Lovitz, 1974; Oltmanns, Broderick, & O'Leary, 1977). In Webster-Stratton's studies of over 400 families with conduct problem children, 75% of the parents reported having been divorced at least once and/or described their current marriage as distressed; half of the married couples reported experiences with spouse abuse and violence. (Webster-Stratton, 1996b). These findings highlight the role of parents' marital conflict and spousal aggression as key factors influencing children's behavior problems. This is corroborated by the earlier work of Rutter et al. (1974), who reported that marriages characterized by tension and hostility were more closely associated with children's behavior disturbances than marriages characterized as apathetic and indifferent.

The role played by marital conflict, as well as parents' expression of negative affect, is further emphasized in studies of couples with children in laboratory situations requiring interpersonal negotiation or conflict resolution (Grych & Fincham, 1990). Studies suggest that factors such as children's exposure to marital conflict (Grych & Fincham, 1990; Porter & O'Leary, 1980), spousal physical aggression (Jouriles et al., 1991; Jouriles, Murphy, & O'Leary, 1989), and child-rearing disagreements (Dadds et al., 1987) account for variance beyond that of general marital stress in a control sample. Katz and Gottman (1994) found an association between high levels of "mutual contempt" or belligerence in couples' relationships and high levels of anger, physical aggression, and noncompliance in the children of those couples. Cummings and his colleagues have demonstrated that exposure to verbal anger and violence between adults is associated with anger and physical aggression in children (J. S. Cummings, Pellegrinia, Notarius, & E. M. Cummings, 1989). When children become sensitized to conflict as a result of repeated exposure to their parents' fights, they are more prone to emotional and behavioral dysregulation (i.e., greater distress and anger) (Cummings & Zahn-Waxler, 1992). These studies indicate the importance of moving beyond the study of individual risk factors (such as marital dissatisfaction and conflict) to the study of risk mechanisms—that is, the underlying processes that cause the risk factor to lead to conduct problems. The important questions then become: which aspect of conflict carries the risk? and, can it be mediated by an affectionate relationship between parent and child or by enlightened parenting?

However, like depression, marital variables appear to interact reciprocally in complex ways with other family and biological factors. For example, the effects of marital conflict and hostility on conduct problems appear to be mediated by the quality of parenting and degree of parental availability (Cummings, Simpson, & Wilson, 1993). Furthermore, Lahey et al. (1988) discovered that the effects of divorce on conduct problems were almost entirely related to parental diagnosis of antisocial personality disorder. Rutter (1986) has called attention to the relationship between marital discord and parental depression, and the possible causal role of marital discord in child behavioral outcomes. One possible hypothesis is that parents' depression affects their children by influencing marital functioning (increasing marital distress); marital functioning, in turn, affects parenting behaviors and parent–child interactions. An alternative hypothesis is that marital distress increases the likelihood of ineffective parenting; this contributes to child conduct problems, which in turn contribute to parental depression and further marital distress.

Certainly, the data suggest that parental depression covaries with marital distress and anger (Hay, Zahn-Waxler, Cummings, & Iannotti, 1992). Both overt and covert anger between parents are more frequent in homes of depressed parents. Depressed mothers have been shown to have more difficulty resolving conflicts than nondepressed mothers (Kochansaka, Kuczynski, Radke-Yarrow, & Welsh, 1987). Instead of attempting to reach compromises as a means of ending conflicts, depressed mothers have been reported to withdraw. However, impaired conflict resolution skills are not limited to the depressed mother. High levels of negative affect and hostility in mothers or fathers certainly can disrupt a couple's ability to resolve conflicts. Moreover, it is further hypothesized that a couple's chronic failure to resolve conflicts leads to increasing negative affect in both parents, which may well contribute to escalating anger in parenting as well as marital interactions. In turn, children who are repeatedly exposed to their parents' negative affect and inability to resolve issues are said to be sensitized, whereby their negative reactions are intensified (E. M. Cummings & Davies, 1994).

A number of investigators are postulating that marital distress (conflict, hostility, etc.) is the primary mediator in the transmission of conduct problems, rather than depression *per se* (Cox, Puckering, Pound, & Mills, 1987). On the basis of their extensive review of the literature on children with depressed parents, Downey and Coyne (1990, p. 68) concluded that "marital discord is a viable alternative explanation for the general adjustment difficulties of children with a depressed parent" (see also Cummings & Davies, 1994). Nonetheless, the precise mechanisms underlying the relationship between marital conflict, depression, parenting, and child adjustment have been little investigated and are poorly understood. This is partially due to the fact that research has consisted largely of global self-report measures of marital satisfaction (or of depression) rather than measures of specific areas of disagreement and close observation of communication and affect. The prediction of child outcomes may be improved substantially by greater specification of how conflict is expressed within families. In a study of 120 families involving detailed observation of marital communication and problem-solving as well as observation of children's interactions with a best friend, Webster-Stratton (1996b) reported a correlation between, on the one hand, high levels of collaboration, engagement, and positive communication in couples and, on the other hand, lower levels of child noncompliance and externalizing problems at home, as well as a correlation between higher levels of positive social skills and conflict management skills and lower levels of negative interactions with peers. Alternatively, negative marital communication, low levels of communication, and poor parental problem-solving between couples were correlated with children's conduct problems at home and their poor conflict management skills with peers. These data provide some support for the notion that a couple's communication patterns in general—and their conflict-resolution style in particular—may be a key variable in the development of their child's conduct problems and peer relationships. This dovetails with the work of Cummings and colleagues (Cummings, Ballard, El-Sheikh, & Lake, 1991; Cummings & Davies, 1994), who found that helping families resolve their conflicts and providing children with explanations of their conflicts (i.e., absolving children from any blame) is helpful for children's emotional adjustment. They conclude that parents' successful resolution of conflicts results in a significant reduction in their children's anger and distress.

(iv) Parenting interactions

Parenting interactions are clearly the most well-researched and most important proximal cause of conduct problems. Research has indicated that parents of children diagnosed as ODD/CD lack certain fundamental parenting or behavior management skills. For example, those parents have been reported to exhibit fewer positive behaviors, to be more violent and critical in their use of discipline, to be more permissive, erratic, and inconsistent, to be more likely to fail to monitor or supervise their children's behaviors, and to be more likely to reinforce inappropriate behaviors and to ignore or punish prosocial behaviors (Patterson, 1982). The most influential developmental model for describing the family dynamics that underlie early antisocial behavior is Patterson's theory of the "coercive process" (Patterson, 1982), a process whereby children learn to escape or avoid parental criticism by escalating their negative behaviors, which in turn leads to increasingly aversive parent interactions. These negative responses, in turn, directly reinforce the child's deviant behaviors. Such mutual training in aversive responding intensifies both the child's aggressive behavior and the parents' hostile, nonresponsive behavior. These findings point also to the importance of the affective nature of the parent–child relationship. There is considerable evidence that a warm, positive bond between parent and child leads to more positive communication and parenting strategies and a more socially competent child (Baumrind, 1971).

Research on family socialization related to aggression increasingly recognizes the bi-directionality of child and parent behavior (Lytton, 1990). It is conceivable that negative parenting behavior is in part a reaction to difficult, oppositional, aggressive child behavior. In a study by Anderson, Lytton, and Romney (1986), mothers of boys with CD were compared with another group of mothers interacting with their own sons, with another boy who had a diagnosis of CD, and with a boy who had no diagnosis of CD. Mothers in both groups were more negative when interacting with the boys with CD, supporting the child-to-parent model. However, mothers of sons with CD were the most negative, suggesting that a history of negative interactions plays an important role (Anderson et al., 1986). The most conclusive evidence for the causal role of parenting interactions in promoting aggressive behavior arises from the research on PT interventions designed to decrease negative parenting behavior. Randomized studies have consistently shown that the risk for conduct problems decreases in groups of parents who received training in more effective parenting skills. These studies will be reviewed in a subsequent section of this paper.

This research regarding family functioning and parent–child interactions argues for parent training programs which attend not only to parenting skills but also to the other interpersonal and relational difficulties of family members. While positive parenting may buffer some of the effects of marital conflict, antisocial behavior, and depression, it would seem logical that if the intervention could also address parental psychopathology and reduce marital conflict, then there might be a greater likelihood for longer-lasting results from intervention.

5.08.2.2.4 Sociocognitive model

One way in which biological and family factors may exert effects on children's behavior problems is through the child's perceptions and evaluations of his or her social circumstances. The seminal work of Dodge and his colleagues has been extraordinarily helpful in suggesting ways in which children process and encode their social experiences (Crick & Dodge, 1994). A series of studies has revealed that aggressive children display deficits in social problem-solving skills (Asarnov & Callan, 1985), define problems in hostile ways, seek less information, generate fewer alternative solutions to social problems, and anticipate fewer consequences for aggression (Rubin & Krasnor, 1986; Slaby & Guerra, 1988). Aggressive behavior in children is correlated with their low empathy for others across a wide age range (Feshbach, 1989). It has also been suggested that children with conduct disorders distort social cues during peer interactions (Milich & Dodge, 1984), including attributing hostile intent to neutral situations. Aggressive children search for fewer cues or facts (i.e., they underutilize cues) when determining another's intentions (Dodge & Newman, 1981) and focus more on aggressive cues (Goutz, 1981). There is also a suggestion in the literature that attributional distortions and underutilization of cues pertain specifically to the subgroup of aggressive children with comorbid ADHD (Milich & Dodge, 1984). It is theorized that the impulsive cognitive style of these children limits their scanning of pertinent social cues before responding, so that they have difficulty perceiving or understanding another person's point of view and are unable to interpret interpersonal situations accurately. This would explain both their lack of social competence and their antisocial behavior. Negative exchanges with peers or with parents then contribute to rejection, further negative responses, and further negative attributions.

These findings argue for the need for PT programs to include ways that parents can teach their children more appropriate social skills as well as how to problem-solve, to control angry responses, and to anticipate negative consequences of aggression. They need to help their children learn to reframe negative appraisals, to detect and express their feelings appropriately, and to learn to take the perspective of another—i.e., develop empathy skills. Parents also need help finding ways to foster more positive peer relationships for their children, such as by inviting friends over and setting up structured home activities, by enrolling them in appropriate community programs, and so forth. These data also suggest the need for PT to be combined with child training (CT), a process whereby children are directly trained in social skills and problem-solving by teachers, school counselors, and parents.

5.08.2.2.5 Environmental model

(i) Insularity and lack of support

Parents' relationships with others outside the family have also been linked to child conduct problems. Studies have assessed both the quantity and quality of maternal contacts outside the home in clinic-referred families of children with conduct problems. Wahler (1980) has used the term "insular," defined as "a specific pattern of social contacts within the community that are characterized by a high level of negatively perceived social interchanges with relatives and/or helping agency representatives and by a low level of positively perceived supported interchanges with friends" (Wahler & Dumas, 1984), to characterize a subgroup of mothers of children with conduct problems. These mothers have been observed to be more aversive and use more aversive consequences with their children than "noninsular" mothers (Webster-Stratton, 1985a, 1985b). Wahler found that on days when mothers reported a high number of contacts with friends (days we might characterize as "noninsular"), maternal aversive behavior and oppositional child behavior was consistently lower than on days when the number of contacts with friends was low (Wahler, 1980).

"Insular" families feel isolated not only from other parents in their communities, but also from their children's schools. They report frequent negative encounters with teachers concerning their children's behavior problems. Such encounters only add to parents' feelings of incompetence, their sense of helplessness regarding appropriate strategies to solve the problems, and their alienation from the school. Parents' inability to collaborate successfully with teachers (and thereby to reinforce them) contributes to teachers' perceptions of parents as uninterested or uncaring in regard to their children's problems. Such blaming attitudes on the part of teachers further escalates parents' sense of isolation and stigmatization regarding their child's problems. The child, in turn, is constantly observing his or her parents' mounting frustration and inability to communicate, as well as his or her teachers' lack of commitment to his family and his learning. This spiraling pattern of child negative behavior, parent demoralization and withdrawal, and teacher reactivity disrupts the connection between home and school and produces a dissonance between the socialization activities of the school and home, further contributing to the child's disengagement from the teacher and from school, and making eventual school drop out a likelihood.

(ii) Socioeconomic disadvantage

Isolation covaries with other important environmental factors that adversely affect family functioning, including economic disadvantage and an aggregate of related risk factors: unemployment, perceived stress, low education, and number of stressful life events. These have been shown to have negative effects on parenting, including the development of abusive disciplinary practices, and on child behavior, including early-onset conduct problems (Hawkins, Catalano, & Miller, 1992; Kazdin & Kolko, 1986; Rutter & Giller, 1983). Low-income parents are more at risk than are middle-income parents for high levels of psychological stress (Gecas, 1979), "power assertive" (i.e., coercive) discipline strategies (Daro, 1988; Trickett, Aber, Carlson, & Cicchetti, 1991), and a tendency to rationalize as legitimate even inappropriate parenting decisions (Hoffman, 1984). It has been argued that "negative parenting behavior is the primary pathway through which poverty undermines children's socioemotional functioning" (McLoyd, 1990). Clearly, child abuse occurs at all income levels; however, there is a higher incidence of physical abuse in families below the poverty line (Straus & Gelles, 1986), even when reporting bias is taken into account. Offord and colleagues found that low income was one of the most significant risk factors for conduct disorder, but that it had its effect on young children, not on adolescents (Offord, Alder, & Boyle, 1986). Moreover, they showed that rates of conduct disorder were significantly higher for children from low-income welfare families than for children from low-income nonwelfare families (Offord, Boyle, & Szatmari, 1987).

Families of children with conduct problems report major life stressors at a rate two to four times greater than families with "normal" children (Webster-Stratton, 1990b). Moreover, parents of children with conduct problems indicate that they experience more day-to-day difficulties than nonclinic families. An accumulation of minor but chronic day-to-day stressors appears to disrupt parenting behaviors and leads to increased rates of coercive behavior and irritability in parents' interactions with their children (Forgatch, Patterson, & Skinner, 1988). Additionally, parents who are depressed, stressed, or demoralized are less likely to be able to provide the cognitive stimulation, emotional support, and social learning necessary to foster a child's positive behavior. Wahler and Sansbury (1990) proposed that highly stressed mothers are less able to screen out extraneous information (e.g., negative interchanges with neighbors or spouse), causing them to react inconsistently or indiscriminately to their children's behavior.

A key issue is whether these environmental factors directly contribute to child behavior problems or whether their effects are mediated by variables such as parenting skills. A synthesis by Capaldi and Patterson (1994) examined a wide array of factors for their predictive relationships to conduct disorders, testing for direct and indirect effects. They found that unemployment, low socioeconomic status, multiple transitions, and high levels of family adversity were related to early-onset conduct problems, but not to late-onset; however, the relationship was less strong when parenting variables were taken into account. The direct effects of low socioeconomic status, in particular, were erased when parenting variables were included; the roles of family transitions, stress, and unemployment also appeared to be indirect. They proposed that environmental variables were related to conduct disorders in a "chain reaction" fashion, whereby unemployment, for example, increased the family stress and the numbers of family transitions, which in turn decreased parental involvement and monitoring and increased the amount of "coercive" parenting. In another study, it was shown that family variables served as a protective factor against risk incurred by high-frequency encounters with significant violence in the neighborhood (Richters & Martinez, 1993). Thus it would seem that the effects of environmental factors on conduct problems are primarily indirect, not direct. However, this is not to discount their importance in explaining the development of conduct problems or their potential impact on parents' ability to sustain consistent and positive parenting.

Again, we see the powerful buffering effects of parenting even in situations of poverty and high levels of stress. But these data also seem to suggest that PT programs which help parents cope with environmental stressors will be more effective and far reaching.

This discussion of etiology relating to conduct problems is concluded by arguing for a complex theoretical model which considers the strong likelihood of transactional, reciprocal relationships among the biological, psychological, familial, sociocognitive, and environmental factors influencing child behavior. In all likelihood, antisocial behavior is not the sum of a certain number of risk factors, but the result of the interaction of multiple risk factors (Hinshaw & Anderson, 1996). Indeed some variables, for example, depression, may be consequences rather than precursors of conduct problems. Furthermore, the interplay of risk is particularly potent for "early-onset" conduct disorder, the course of which leads to more serious delinquency (Quay, 1986). Such a complex model will necessitate a family intervention which takes into consideration all of these intertwining factors.

5.08.3 DESCRIPTION OF INTERVENTION PROCEDURES AND PROPOSED MECHANISMS OF CHANGE
